with a value of 3.460 and a p-value of 0.063, similarly suggested a marginal association, just missing the 5% cutoff but significant at 10%. The Fisher's Exact Test (p = 0.082) and Linear-by-Linear Association (p = 0.063) tests both indicate a significant result at the 10% level, reinforcing the idea of a weak association between the variables (tab. V).

TABLE V.
The correlation between HRCT pattern and DLCO.

HRCT	Normal DLCO	Decreased DLCO	Total
No specific pattern	10 (58.82%)	7 (41.18%)	17
Specific pattern	14 (32.56%)	29 (67.44%)	43
Total	24 (40.0%)	36 (60.0%)	60 (100.0%)

DISCUSSION

In the last decades, RA has won its leadership among systemic inflammatory autoimmune diseases, the prevalence of pulmonary involvement increasing. Nowadays, modern medicine has the necessary tools for an early and correct diagnosis (3, 6). ILD is diagnosed more frequently in RA patients presenting risk factors such as: an active smoking status, male gender, advanced age and high ACPA titer (6, 19).

EAM in RA represents a factor of disease severity, lung damage proving to be more and more frequent and increasing the risk of death up to 3 times (20-22). Although the new therapeutic strategies are promising, the mortality rate is still high (23). Even though the patients are mostly asymptomatic, at least 27-63% will have low values of lung function tests, especially DLCO decrease (6, 24). Regarding the changes highlighted by HRCT scan, symptomatic patients present in 90% of cases an ILD pattern, but even asymptomatic ones can have non-specific changes in a high percentage of up to 68% (25). Moreover, regardless of the stage of RA activity, the changes observed on HRCT can anticipate the decrease of pulmonary functionality (26). A decreased DLCO has been correlated with a progressive RA-ILD disease, being the most sensitive independent predictor of this association (6, 27).

The objective of our study was to highlight the correlations between different parameters of RA and the type and severity of the lung involvement. The positivity of ACPA seems to be the most important risk factor for the development of pulmonary damage in the analyzed group of patients. The increased values of ACPA were correlated with the decrease of DLCO as well as with the appearance of specific pulmonary interstitial changes highlighted by HRCT. In addition, interstitial lung disease was associated with functional impairment quantified by DLCO, the low values of this parameter being closely related to the occurrence of ILD on HRCT.

In a multicenter cross-sectional study carried out over a period of 2 years, Mena-Vázquez *et al.* (28) found a certain predisposition for ILD in RA patients with a history of smoking (p=0.013) and with ACPA positivity (p=0.004). Also, in the group with RA and lung damage, the ACPA titer and DLCO decrease below 70% were correlated with the occurrence of articular erosions (p<0.001). Moreover, the authors described the characteristic aspects

highlighted on HRCT as follows: UIP pattern in 66% of cases and NSIP pattern in approximately 32% of subjects (28-31).

Our results are in accordance with the data from the literature and support the close relationship between RA and ILD. The patients included in the analysis were mostly women (76.7%), with an increased level of ACPA, with specific lung changes on HRCT (71.7%) and with a decrease in lung function described by a decrease in DLCO (60%). A distinctive fact is represented by the non-smoker status, which was more frequently present in our cohort.

Supporting the same idea, Zhang *et al*. (32) evidenced a decreased DLCO in 92% of patients with RA-ILD. Kim *et al*, whose study took place over a period of 7 years (2001 - 2008), pointed out the close connection between ILD and RA and described an equality between the 2 distinctive patterns UIP and NSIP (33). Another study that focused on the HRCT aspect highlighted that the most frequent findings were UIP aspect (37.22%) and also NSIP aspect (25.94%) (34). The study included 266 RA-ILD subjects, mostly women (n=162; 60.90%) with a mean age of disease onset at 64.80 ± 10.71 years old. The percentage of smokers was higher among males (75.92%) (34).

Other data that confirm the results obtained from our study, were published by Samy (35). He analyzed 160 cases with RA, of which 85% were women, with a low DLCO, with high ACPA titer and with specific HRCT changes of interstitial damage. The published data reinforce the link between all these parameters and the appearance of RA-ILD (35). Moreover, Paulin *et al*. showed, in a multicenter cross-sectional study on 83 subjects (mostly women - 83%), with a mean age of 46.49 years, the association between a decreased DLCO, an increased ACPA level and pulmonary impairment (36). Last but not least, Oak *et al* (37) and Bessa *et al.* (38), through their studies, support this close link between ACPA high level - low DLCO - HRCT changes, which can be considered an axis in the development of RA-ILD.

Our study has some limitations due to the small number of enrolled subjects. However, we highlighted important aspects regarding RA-ILD. Some of our results did not have statistical value but can open new perspectives on the horizon of knowledge. The presence of ACPAs in high titers correlated with the decreased levels of DLCO and the presence of specific patters on HRCT scan, may be considered significant predictors of pulmonary impairment in RA.

CONCLUSIONS

This prospective study highlighted that seropositivity tends to be more prevalent among patients who have a decreased DLCO and a specific lung pattern on HRCT, thereby indicating a potential lung impairment. The positivity of ACPA seems to be the most decisive risk factor in the development of RA-ILD disease. The clinical and paraclinical evaluation of these patients is particularly important and the presence of EAM should not be neglected. The association between RA and ILD is a certainty that worsens the evolution of the disease and increases mortality. Therefore, an early diagnosis and an appropriate treatment, which requires a multidisciplinary team, becomes a priority in everyday medical practice.

INSULIN PUMP THERAPY REDUCES THE SEASONAL HBA1C DRIFT IN CHILDREN WITH TYPE 1 DIABETES (Abstract): Glycated hemoglobin A1c (HbA1c) levels are known to fluctuate seasonally in children with Type 1 Diabetes (T1D), typically decreasing during warmer months and increasing during colder months. Given that continuous subcutaneous insulin infusion (CSII) may lower HbA1c by approximately 0.3% (3 mmol/mol) relative to multiple daily insulin injections (MDI), the well-documented seasonal drift might offset the immediate benefits of initiating CSII in warm seasons. This study examines how CSII and MDI each modulate the expected rise in HbA1c from warmer to colder weather. **Materials and methods**: A total of 504 T1D patients under 18 years old attending the pediatric diabetes department of a major university hospital were evaluated. Exclusion criteria included disease duration under 1 year, lack of continuous glucose monitoring (CGM) access, fewer than 6 months on CSII, or incomplete data. Propensity score matching was used to yield two groups (CSII versus MDI), matched by age, HbA1c, body mass index, and calendar month (n=65 in each group). Follow-up visits occurred at 180±90 days after baseline. **Results:** Follow-up time was comparable in both groups (174±35 days for CSII *vs.* 169±38 days for MDI, p=0.44). Children in the CSII group demonstrated no significant change in HbA1c between baseline and follow-up. Conversely, the MDI group exhibited a statistically significant increase in HbA1c at follow-up (7.58±1.0%; p=0.01 *vs.* baseline). Among adolescents, the same pattern emerged, indicating a stable HbA1c level in the CSII group and a marked rise in MDI users (p=0.01). **Conclusions:** Children receiving MDI experienced the expected seasonal HbA1c increase, whereas CSII users did not demonstrate significant changes. These findings highlight the potential buffering role of CSII on seasonal HbA1c drift, even when follow-up conditions and baseline characteristics are comparable. **Keywords:** PEDIATRIC DIABETES, INSULIN PUMP, HBA1C SEASONALITY.

INTRODUCTION

Diabetes mellitus continues to be a significant public health problem, although diabetes-associated mortality rates seem to be declining in recent years (1). Despite the increasing recent recognition of time in

range importance, glycated hemoglobin A1c (HbA1c) is still the pillar of glycemic control evaluation in type 1 diabetes mellitus (T1D) in children. In many temperate regions worldwide, HbA1c levels exhibit seasonal variations, with lower values observed in the second and third quarters compared to the rest of the year (2-8). In addition, HbA1c variability tends to be greater in countries that experience a more prominent contrast in temperatures between winter and summer (5,9).

As costs and access improve, continuous subcutaneous insulin infusion (CSII) using an insulin pump may become the primary treatment option for children with T1D. Compared with multiple daily insulin (MDI) treatment, its advantage on HbA1c of approximative 0.3% (3 mmol/mol) is strikingly similar to the average differences in HbA1c induced by seasonality (2,10). Consequently, initiating CSII in summer might not translate into an immediate HbA1c benefit simply because of the known summer-winter HbA1c inherent drift. CSII appears to ameliorate HbA1c seasonality, but a direct comparison with MDI on this aspect is still missing (7).

Researchers should carefully consider these aspects when using descriptive data from real-world registries. Therefore, we tried to contribute data to the general knowledge about the impact of CSII and MDI on the HbA1c expected increase from warm to cold seasons. The primary outcome of the current study was to assess short-term (six months) changes in HbA1c starting from the second and third trimester of the year in T1D children treated with either CSII or MDI. Secondary outcomes included changes in the total daily insulin dose, the prandial-to-total insulin ratio, and the units of insulin per kilogram of body weight.

MATERIALS AND METHODS

Study population. This retrospective observational cohort study compared the short-term metabolic control in type 1 diabetes children on either CSII therapy or MDI. All patients attending the pediatric diabetes department of a major university hospital from 2019 to 2024 were eligible for this study (n=504). This major pediatric diabetes center serves a large urban area and its surroundings within a 300 Km radius. As part of the larger SWEET Project (www.sweet-project.org), the local pediatric diabetes registry contained information on anthropometrics, biochemistry, and therapy, including data before 2019. As continuous glucose monitoring (CGM) was known to impact metabolic control significantly, patients were required to have continuous CGM access to be eligible for this study. Other exclusion criteria at baseline were age 18 or more, diabetes duration under one year, and time since CSII initiation less than 180 days.

The study has been conducted in accordance with all the relevant national regulations and institutional policies and with the tenets of the Helsinki Declaration, and the local Ethics Committee has approved it. Informed consent was obtained from all legal guardians of individuals included in this study.

Baseline. The baseline was defined as the first available recording, in which the age was less than 18 years, the diabetes duration was 365 days or more, CGM was used, and the date of visit was in the second or third trimester of the year. Propen-

sity score matching was used to control differences in age, diabetes duration, HbA1c, BMI and calendar month at baseline in a 1: 1 group ratio. The final cohort retained 130 subjects, split into a CSII (n=65) and an MDI group (n=65) based on the baseline insulin delivery method (see fig. 1). The MDI group was formed using the remaining patient pool after constructing the CSII group. The treatment option at baseline had to remain unchanged at the follow-up visit.

Follow-up visits occurring at 180 ± 90 days after baseline were eligible for this study. Where multiple follow-up visits were available, only the one closest to 180 days was retained in the primary analysis. Patients without at least one follow-up visit were excluded (n=52) (fig. 1).

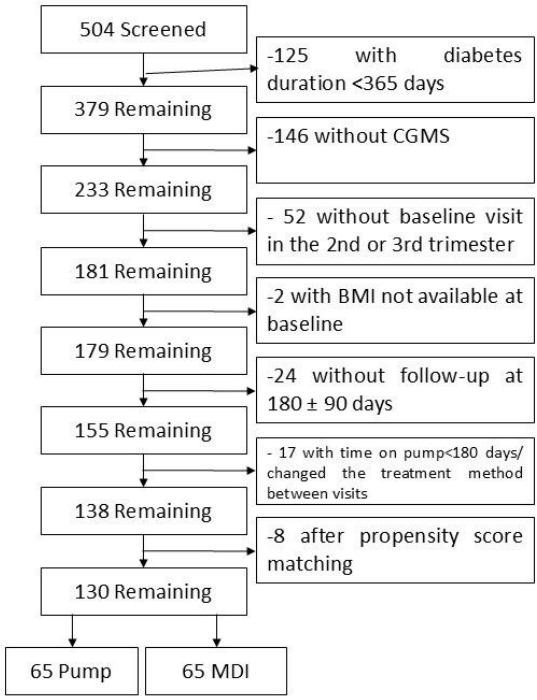

Fig. 1. Flowchart of patient attrition in the study. (CGMS: continuous glucose monitoring system, BMI: body mass index, MDI: multiple daily injections)

Statistical analysis was performed using *SPSS version 29.0.1.0*. A 2-sided p-value less than 0.05 was considered statistically significant. Propensity score matching used the multivariable logistic regression model. Only patients with baseline and follow-up data were retained when individual variables were analyzed. Primary outcome variables were available in all study subjects. The primary outcome was supplementary checked in a sensitivity analysis, using all available follow-up visits at

180 ± 90 days after the baseline. This analysis was performed to check the reliability of the main results.

The primary outcome was further explored in the adolescents' group, defined as age at baseline between 10 and 17 years (n=79). Preadolescents could not be investigated due to the limited number of patients in this age category.

Secondary outcomes were investigated in a subgroup of patients (n=53 CSII and n=58 MDI) due to missing information in some patients. The number of sick days over the last three months was available in a limited patient sample (n=27) containing a mixture of CSII and MDI patients. Due to the limited number of cases, the Wilcoxon matched-pairs signed-ranks test was used in this subset of data.

RESULTS

Primary outcome. The final cohort retained 130 subjects, respecting all the inclusion and none of the exclusion criteria. Mean age was 10.7 ± 3.5 years, with a diabetes duration of 4.5 ± 2.8 years. In the CSII group, the baseline mean time since pump initiation was 858 ± 491 days (range 193-2327 days). Propensity score matching was responsible for the similar results at baseline for age and HbA1c among pump users (n=65, mean age 10.7±3.7 years, HbA1c 7.28 ± 0.9%) and MDI users (n=65, mean age 10.7±3.4 years, HbA1c 7.35 ± 1%; all p>0.05 *vs.* CSII), (tab. I).

HbA1c at baseline was also similar between the two groups in adolescents (7.23 ± 0.9 CSII *vs.* 7.32 ± 1 MDI).

The mean follow-up was similar in the CSII (174 ± 35 days) and the MDI group (169 ± 38 days, p=0.44). HbA1c at the follow-up visit was similar to baseline in the CSII group. However, the MDI group experienced a statistically significant rise in HbA1c at the follow-up visit (7.58 ± 1%, p= 0.01 *vs.* baseline) (tab I). The supplementary sensitivity analysis using all available follow-up visits occurring 180 ± 90 days after the baseline did not change these results.

Adolescent restricted analysis showed the same pattern: no significant changes from baseline in the CSII group (7.23 ± 0.9% *vs.* 7.4 ± 0.8 %, p=0.93), but a significant rise in the MDI users (7.32 ±1.0% *vs.* 7.63 ± 1.1%, p=0.01).

Secondary outcomes. The total daily insulin dose at follow-up increased significantly in both CSII (+4.5U, 95%CI 1.7-7.3, p=0.02) and MDI group (+3.5U, 95%CI 1.4-5.5, p<0.001), see Tab I. During the follow-up, the prandial to basal ratio remained relatively unchanged (p>0.05). MDI group had a significantly higher prandial to basal ratio as compared with pump users at baseline (p<0.01), but not at the follow-up visit (p=0.173). During the follow-up, the CSII group showed a significant increase in insulin per body weight (p=0.02), accompanied by significant increases in BMI (p=0.006), weight (+2.2Kg, 95%CI 1.5-2.8, p<0.001), and height (+2.4 cm, 95%CI 1.9-2.9, p<0.001). The MDI group experienced an increase in insulin per body weight (p=0.041), weight (+2.1 Kg, 95%CI 1.5-2.7, p<0.001) and height (+3.2 cm, 95%CI 2.4-4, p<0.001), but not BMI (p=0.131).

There was a significant rise in the number of sick days from baseline (1.2, 95%CI 0.2-2.4) to follow-up visit (7.1, 95%CI 3.7-11.3, p=0.005). Data could not be further detailed by the treatment group.

TABLE I.

Baseline and follow-up characteristics of children with type 1 diabetes

	Insulin pump		Multiple daily injections

^{NS} not significant; * p<0.05; ** p<0.01 *vs.* baseline; P: B ratio - prandial to basal insulin ratio; IBW - insulin per body weight; BMI - body mass index

DISCUSSION

This observational study investigated the hypothesis that CSII (n=65), MDI (n=65), or both could change the natural rise of HbA1c from warm to cold seasons in children with T1D and uncovered three major findings. First, children on MDI treatment experienced the expected rise in HbA1c during follow-up. Second, the CSII group did not show a significant rise in HbA1c despite similar follow-up conditions. And third, BMI showed different dynamics in CSII compared with the MDI group.

Seasonal variation in HbA1c is an important concept, especially in older children with T1D from world regions with a high temperature contrast between winter and summer (5, 11, 12). Primary contributors to higher HbA1c in cold seasons might be increased susceptibility to viral infections, winter celebrations related to excessive eating, school stress, and decreased physical activity (3, 11, 13, 14). Parallel variation in blood pressure, lipid profile and insulin sensitivity might also contribute to some seasonal variations in HbA1c (12, 15, 16).

Moreover, some children have an acute recovery of insulin secretion a few days after insulin initiation following T1D onset. Insulin requirements may drop significantly, and sometimes the patients can live insulin-free for a limited amount of time. This partial or total remission may last for a couple of weeks or months but rarely exceeds one year in children. HbA1c levels and variability are exceptionally low during this period but sharply rise following its end. The current study enforced at least one year of diabetes duration at baseline, but most children had significantly more than that. The total number of sick days over the previous three months was used to proxy

for viral infection incidence. Although results could not be detailed by treatment group, this important parameter did rise significantly in the limited sample of patients investigated. No data was available for physical activity, but the authors' observation is that summer is associated with increased leisure-related physical activity compared with late autumn and winter.

Cold stress-related rise in mean glucose levels, asserted by HbA1c, might also be explained by increased glucagon, epinephrine, cortisol, growth hormone, and thyroid hormones plasma concentrations as a natural adaptation to the body's demand for heat production (17-19). Besides increased levels, resistance to glucocorticoid action was described as an adaptation to a cold environment (19). Increased counter-regulatory hormone concentrations translate into a parallel increase in insulin resistance during the cold seasons and, ultimately, in HbA1c variability (19).

The results from a retrospective observational study by Tanaka *et al*. indicate that insulin pump treatment may significantly reduce seasonal variation in HbA1c levels. The researchers examined the seasonal variation of HbA1c levels and how the COVID-19 pandemic and related restrictions affected this variation in a cohort of 52 adults with T1D. The study found that individuals using CSII and sensor-augmented pumps experienced the least seasonal variation in HbA1c levels. In contrast, greater variability was observed in groups using MDI without CGMS or with intermittently scanned continuous glucose monitoring. Notably, variability in HbA1c levels was present in 2019 but diminished in 2021 during the COVID-19 restrictions (20).

In an observational study on 454 T1D children, 231 on CSII and 223 on MDI, Fendler *et al.* found a significantly lower HbA1c variability in the CSII group compared with the MDI group (21). Although similar to results from the current study, they used a different approach to assess HbA1c variability, i.e., the mean standard deviations of the mean HbA1c during the mean three years follow-up. Also, they declared that only acute hospitalizations were considered during the follow-up, disregarding the scheduled hospital admissions. Adding the age imbalance at baseline, with the MDI group being around two years older than children on CSII, results might express the expected higher HbA1c variability in older T1D children when admitted to a hospital for an acute presentation. The current study used propensity score matching to control for age and other possible imbalances between groups. Results can also be interpreted for situations outside acute presentations in the hospital.

As strength points, this study used propensity score matching to control for important confounding variables. Besides enforced similar age, HbA1c, BMI and calendar month at baseline, the protocol excluded patients with no access to CGM, recognizing the importance of this confounding variable on HbA1c. The influence of partial remission phase was minimized by enforcing at least one-year duration of diabetes at baseline. HbA1c variability due to MDI to CSII switch was accounted for by including only patients with at least 180 days since insulin pump initiation.

As weak points, this study was performed in a single center, with a limited selection base (N=504). The number of cases retained in the final groups was also limited (n=65 each). Moreover, it did not

evaluate gender impact on HbA1c dynamic in studied groups. Although many girls (especially adolescents) seem to have slightly higher HbA1c levels than boys starting right from T1D onset, no gender differences were previously reported in studies investigating HbA1c variability (3, 11, 22). Information on physical activity and incidence of viral infections was not available. These parameters are part of the possible explanations of HbA1c variability. The number of sick days in a limited sample of patients from both investigated groups only offered limited compensation for this shortage. Although there is no obvious indicator that physical activity and viral infections differed substantially between the CSII and MDI groups, no direct systematic measurements were available.

CONCLUSIONS

In conclusion, children receiving MDI experienced the anticipated seasonal HbA1c increase, while CSII users exhibited no significant changes. These findings emphasize the potential buffering effect of CSII on seasonal HbA1c drift, even when follow-up conditions and baseline characteristics are similar. Pediatric endocrinologists and researchers should recognize the seasonal variability in HbA1c and the potential impact of CSII on modifying this phenomenon when used alongside CGM.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

CHALLENGES IN MANAGING DIVERSE GENDER ROLES AMONG ROMANIAN MEDICAL PROFESSIONALS (Abstract): This original research examines the perceptions and attitudes of Romanian medical professionals towards gender nonconformity, focusing on stereotypes and their implications for healthcare delivery. The **aim** is to identify cultural and psychological barriers that influence healthcare delivery to gender diverse individuals and to propose educational strategies for improving inclusivity and non-discrimination. **Materials and methods:** Through a qualitative, phenomenological approach, the research explores stereotypes and conformity to assigned gender roles among a sample of medical students that were evaluated through interviews focusing on personal and professional views shaped by cultural, familial and societal influences. The study combined systematic literature reviews from international databases with a transversal study involving 50 medical students aged 20-52 years. Participants' views on traditional axioms and other popular gender stereotypes were critically evaluated to identify variations across age, gender, marital status and cultural background. **Results:** Results showed that gender role conformity is prevalent, particularly among married and religious participants, underscoring the influence of traditional patriarchal norms on societal integration. The findings emphasize the need for specialized education to foster acceptance and tolerance toward gender diversity. Addressing cultural stereotypes and providing adequate training are critical for developing ethical medical practices that ensure equitable care for all patients. The findings highlight the urgent need for specialized education to dismantle stereotypes, improve professional competence and foster ethical medical practices. **Conclusions:** This research concludes that recognizing and addressing gender role biases is pivotal in reducing stigma and ensuring equitable care for nonconforming individuals within the Romanian healthcare system. **Keywords**: HEALTHCARE ETHICS, MEDICAL PROFESSIONALS, GENDER DIVERSITY, INCLUSIVE EDUCATION, GENDER STEREOTYPES.

INTRODUCTION

In Western modern societies, the visibility of gender incongruence is mostly reflected in the phenomena of nonconforming gender roles. Sometimes such persons face challenges in accessing medical care. This can be a problem of limited competence among medical professionals or of

stigma rooted in traditional intolerance. Therefore, medical proper education in gender care is important for medical professionals (1).

In Romania, gender healthcare is still in its infancy. We need education for social acceptance and integration. The issue of the relationship between those persons and healthcare providers is much debated in the international literature (2).

This research explores the stereotypical perception of gender-assigned traits among medical professionals, which can provide information about their attitude towards nonconforming gender patients who need care. We believe that our medical staff has limited knowledge about the subject. We wanted to see whether they understand and accept gender nonconformity, because this might be the first step to adjust their medical attitude towards nonconforming gender people. We tend to address the psychological barriers of medical stuff, because they need to ensure ethical and adequate medical care for all. Gender nonconforming roles remain unfamiliar and challenging concepts for many (1, 3, 4, 5). Worldwide contemporary evolutions seem to preserve and even amplify the phenomenon of gender nonconformity and there will probably be many people in need for general and specific medical care. Therefore, recognizing acceptance and respecting the diversity of gender experiences and expressions should be the trigger point to empathetic psycho-behavioral responses, supporting professional competence (6). We believed that the gender roles assumed by medical professionals inevitably shape their attitudes toward individuals with diverse gender identities.

Gender role is conditioned by "cultural and historical traditions, ethnic particularities, stereotypes and norms related to sexuality" (7). Nowadays, changes in gender role affirmation, fully recognized in many modern "progressive" societies, influence social, economic, and political life. But, nevertheless, there still are persistent stereotypes, which perpetuate inequalities and discrimination. Gender roles shape self-image and societal integration, varying across cultures and are influenced by stereotypes that simplify complex ideas and resist change (8, 9, 10).

As cultural constructs based on sexual differentiation, they are seen as "natural" or "appropriate" (10, 11). These stereotypes, perpetuated through education, media, and family traditions, reinforce distinctions between sexes (4). Historically, religion and cultural norms have cemented these differences, assigning women subordinate roles. Patriarchal views have been used to justify discriminatory practices in Romanian culture, too (12, 13). Rejection of nonconforming gender identities is strongly linked to religious fundamentalism, often cited as a root cause of homophobia and aggression (14).

Authors believe that traditional gender role stereotypes limit personal development. Joseph Pleck's "fragmentation" of gender roles highlighted their adaptability, reducing conflicts and enhancing psychological well-being (12). Researchers recommend that specialized gender diversity education should be introduced in the professional training of medical staff (1, 5).

Professional training and continuing medical education often lack explicit information on the specific needs of gender diverse individuals, resulting in limited understanding of specialized care (1, 15).

International studies highlight that nursing, a predominantly female role (5, 11, 16, 17, 18), has women significantly outnumbering men, as reported by the World Health Organization (19).

This stereotype has historically exclud-

ed men from nursing (4, 19, 20, 21, 22, 23). While professional value in healthcare is often influenced by gender, feminine traits are sometimes seen as less experienced, while masculinity is associated with leadership. However, Kirchmeyer's study shows that femininity can predict professional dedication, fostering innovation, patient focus, and effective teamwork, complementing leadership qualities linked to masculinity (18).

As international databases show, cultural norms that have historically tied caregiving roles to women are reflected in our study too (mostly women participants). A 2021 analysis (24) shows that women dominate healthcare executive roles but are less likely to achieve higher professional or academic ranks (25, 26). Men are often perceived as better leaders (27), while women in medical professions frequently experience higher rates of burnout (28). This is about women's efforts to balance professional responsibilities with traditional roles as mothers and homemakers (29). Women are approached differently than men in medical training, both by educators and patients, as well as by patients' families (30, 31).

Medical students are evaluated differently based on gender stereotypes, with male achievements often labelled as "leadership" while women's efforts are categorized as "team focus" and "caring ability (32)." Research on women in healthcare shows they prioritize collaboration, consensus, and work-life balance, often juggling family and professional roles. Men, conversely, emphasize career advancement and recognition (33, 34, 35).

As society increasingly embraces gender role diversity, it is essential for medical staff to recognize and address both stereotypical and nonconforming roles that individuals embody in their lives. Acknowledgment of the fact is important to psychological well-being and societal balance (23). Also, international literature highlights the importance of psychological traits and gender role identity assumption for career development. Gender role conformity, shaped by "social axioms" affects medical workers. These stereotypes of rigid traditional roles can lead to resistance and intolerance, especially as gender diversity becomes more visible, so educating medical staff to manage culturally influenced stereotypes is crucial for fostering acceptance and delivering inclusive care.

Gender roles evolve with changing societal norms, challenging the belief that men and women were inherently created for specific roles. Diversifying gender roles improves psycho-emotional balance, benefiting individuals, including those in the medical field (35).

Traditionally, women managed caregiving and households, while men provided financially. Although roles are now more flexible, gender inequality persists. In Romania, conformity to religious values shapes coping mechanisms and identity but often resists gender diversity. Addressing gender stereotypes among healthcare workers is key to improving care for nonconforming individuals and guiding trainees toward ethical, inclusive practices.

The hypothesis of the research was that the stereotypical views held by medical professionals about gender-assigned roles shape their expectations and attitudes towards nonconforming gender patients.

MATERIALS AND METHODS

First, we performed a review of international literature from PubMed and ScienceDirect databases using specific search terms like "gender role", "transgender healthcare" and "gender nonconformity." Systematic reviews published between

2020 and 2023 in English that were open access were included. To refine results, combinations of terms were used, followed by sorting abstracts and analysing full texts. A limitation identified was the scarcity of studies linking the proposed concepts, as most focus on individual topics.

We performed a qualitative transversal study which utilized a convenience sample of 50 third-year medical students. Voluntary participation ensured informed consent, while anonymity and confidentiality were maintained. The phenomenological approach explored stereotypes and social axioms on gender roles ("The man is the head of the family"/ "The man must ensure family safety"/ "The woman looks after the household and the children"/ "Women should obey their husband/partner"). Written responses and oral in-depth interviews allowed participants to express authentic perspectives. Open-ended questions addressed conformity to gender roles and correlations with daily life, covering professional, familial, and societal dimensions. The free text interview method was selected so that participants could provide responses in their own words, allowing for rich, detailed and authentic data.

Secondary analysis compared psychological traits identified in participants with those documented in established Romanian studies. Insights were gathered on how medical education and cultural exposure affect tolerance and receptiveness to gender diversity. The open-ended questions were formulated on the basis of the general stereotypes assumed by the respondents and aimed at assessing the presence of the qualitative phenomenon of conformity to the assigned gender role, as a starting point for accepting the diversity of nonconforming gender roles, which we are currently facing mostly in Western culture. The free expression of the conceptions was correlated with the evaluation of their concordance with concrete aspects of the practitioner`s life and work (declared and/or observed by the researcher): living environment, marital status, children, declared practice of traditional religious rituals, general level of medical education, involvement in the debate on the proposed gender role nonconformity topics, level of information about them, interest shown in the proposed topics, frequent reference to dogmas, refusal to debate the proposed topics, circumstantial answers, indicative level of knowledge of the general duties of their profession.

Data were analyzed using Colaizzi's method, identifying key themes, formulating meanings, and verifying results with participants for accuracy. This qualitative phenomenological interpretation emphasized lived experiences and perceptions, shedding light on the intersection of gender roles and healthcare practice. The design of the study was to utilize interpretative phenomenology, in order to explore the lived experiences and perceptions of medical students regarding gender nonconforming individuals. Ultimately, the findings highlighted cultural influences, conceptual conformity to traditional gender roles, and the need for inclusive education to address diversity in healthcare.

RESULTS

The study group consisted of 50 medical students, predominantly women (45 females, 5 males) aged between 20-52 years old. Most participants were aged 20-29, many already engaged in healthcare roles or training, with complex life experiences. Seven women over 40 years of age stood out for their broader perspective on healthcare, often pursuing higher education for professional advancement. Out of the 50 students, 33 were employed in various medical fields, including ICU, surgery,

ambulance services and oncology, while 15 were high school graduates in basic training. The employed students demonstrated confidence and firm beliefs but had limited knowledge on gender nonconformity topics. Resistance to discussing gender roles was noted among older professionals. Male participants displayed moderate interest and restraint on these topics.

Most students (46 people) were urban-based. Marital status revealed 24 married women, 9 single, 7 divorced, and 4 in consensual relationships, with gender nonconforming traits observed but often unrecognized by respondents. Of the women, 28 had children, with 5 pregnant during the study.

Regarding confessional affiliation, all participants identified as Christian, with the majority being Orthodox. Qualitative analysis showed familiarity with patriarchal concepts like "the man is the head of the family", with 23 participants agreeing in principle, including 20 women and 3 men. Traditional views were juxtaposed with evolving roles, such as professional aspirations, partially challenging traditional gender norms. The study highlights that 75% of married female participants (15 out of 20) supported patriarchal views, despite having independent careers. Younger women (aged 20-39) showed a mix of traditional and modern influences, with cultural and religious upbringing shaping perceptions. Of 5 male participants, 3 upheld patriarchal views regardless of marital status. 8 women, aged 20-39, and 2 men categorically opposed patriarchal axioms, while 11 respondents showed ambivalence, acknowledging a need for family structure without assigning dominance to men. Agreement on stereotypes like "the man must support his family" was prevalent among 35 women and 3 men, mostly aged 20-39, during career-building years.

Stereotypes about women's roles in household and child care were evident in 29 women and 3 men, reinforcing traditional norms while reflecting partial change in role perceptions. Among 13 exceptions, 11 women aged 20-29 and 2 aged 30-49 deviated from stereotypical gender axioms, reflecting modern trends toward diversifying family roles. Notably, 5 young women rejected these axioms, while 3 women remained neutral.

DISCUSSION

Analysis identified agreement with two social axioms: "Women should obey their partner/husband", supported by 15 women (mostly aged 20-29) and 2 men, influenced by spiritual and cultural education. However, 30 women and 2 men disagreed with the obedience aspect while acknowledging respect for traditional family roles. Male participants displayed ambiguous interpretations, revealing discomfort with nonconforming gender roles in healthcare. Positive discrimination in favor of traditional male roles was accepted by 15 women, while 30 rejected such biases.

Further, two broader axioms were analyzed. For the statement: "A woman ought to get married" we noticed: 35 women and 4 men agreed, thus in accordance with the stated social axiomatic concept, as follows: 16 women in the 20-29 age group, 12 women in the 30-39 age group, and all women in the 40-50 and over age groups, respectively all men except one in the 20-29 age group, who did not express an opinion. So, 39 people out of the total of 50 in the researched group agreed with the stated social axiom, and out of the total of 45 women, 35 said "yes". Out of the 16 women agreeing with the axiom aged 20-29, 9 were married, 1 in consensual relationship, 2 divorced and 4 singles. Of the 12 women in the 30-39 age groups agreeing with the

axiom, 9 were married and 2 divorced, and in the 40-49, 50 and over age groups, 2 were married, 3 divorced. So, the marital status 'married', present in 21 respondents out of 35, is a predictor of gender role conformity in the study group. Disagreeing with the traditional axiom were 10 women, 9 of them aged 20-29 and 1 in the 30-39 age group, mostly single.

The interpretation of the axiomatic concept: 'It is better to stay in an unsuccessful marriage than not to marry at all', provided the following results: Agreeing were 21 women and no men, as follows: 10 women in the 20-29 age group, 8 in the 30-39 age group, and 3 in the 40-50 and over age groups, 16 married. All of them, either have children, or were pregnant at the time of the study. Disagreeing were 22 women, of whom 8 were married and 3 had children, and all 5 men. Two were undecided or avoided the answer. Approximately the same extent female students related to the traditional concept of marriage as a necessity regardless of the quality of the relationship, a deeply stereotypical cultural gender-role aspect. The status of "married" almost equally influenced the critical attitude towards the "unsuccessful" nature of marriage, which for women who disagree with the concept, represents a nonconforming feature of their gender role. All 5 men expressed disagreement with this social axiom, which is applicable not only to women but to men as well, a nonconforming aspect of the male gender role as well.

Furthermore, 21 women and 3 men who had children stated that they take care of their children's education and share household chores. These, doesn't confirm the discussed stereotype.

The strongest acceptance of cultural gender stereotypes occurred for "the man has to ensure family security" "the woman takes care of the household and the children" and "a woman ought to get married." These align with traditional societal norms, showing high conformity among medical students. Notably, 34 out of 50 participants agreed with "The man is the head of the family," further reflecting paternalistic conceptions.

The lowest acceptance rates were for "Women should obey their partner/husband" and "It is better to stay in an unsuccessful marriage than not to marry at all," representing modern, non-discriminatory perspectives. The contradiction between declared traditionalism and low acceptance of subservience highlights participants' mixed understanding and awareness of these stereotypes.

The in-depth interviews revealed correlations between gender role perceptions and participants` daily family and professional life. They included: married women balancing healthcare careers, household duties, childcare, and advanced studies, as well as single/divorced mothers, women in consensual relationships, and women pursuing medical specialization while working non-medical jobs. Nonconforming traits observed included explicit or partial disagreement with traditional axioms, career dedication reducing household responsibilities, single-parenting, female breadwinners, male nurses, men sharing household chores and childcare, and divorcees. These findings illustrate deviations from traditional gender roles.

CONCLUSIONS

Gender roles and their diversification are increasingly relevant in Romanian society but remain poorly understood among medical professionals, risking intolerance and discrimination. This study emphasized that adherence to traditional roles is mostly linked to divinatory practices, and the majority of married participants supported

patriarchal views despite pursuing education and careers. Younger participants displayed a mix of traditional and modern influences, shaped by cultural and religious factors and only a minority categorically opposed patriarchal beliefs. Many participants were unaware they practiced diverse gender roles and only recently began exploring this subject. Specialized education is critical to address gender role ideologies, prevent discrimination, and promote acceptance in professional and societal contexts, ensuring a respectful and adequate conduct in medical care.

EXPLORING SUICIDAL MOTIVATION IN PATIENTS WITH DEPRESSION. A COMPREHENSIVE ANALYSIS OF THE PSYCHOLOGICAL, SOCIAL, AND BIOLOGICAL FACTORS INVOLVED (Abstract): Depression is a prevalent and severe mental disorder affecting millions globally, significantly increasing the risk of suicide, which is the second leading cause of death among young individuals. **Aim:** This study examines the complex interplay between depression, anxiety, personality disorders, and suicidal behavior, highlighting the multifaceted nature of these relationships. **Materials and methods:** Utilizing a sample of 40 patients diagnosed with depressive episodes, both in isolation and as part of major depressive disorders or bipolar disorders, the research investigates various psychological, social, and biological factors contributing to suicidal ideation. The findings underscore that not all individuals with depression exhibit suicidal thoughts, yet specific risk factors including neurochemical imbalances, low self-esteem, and social isolation are prevalent. A primary focus of the research is the declared suicidal motivation of each patient in relation to the identified factors, offering insights into the motivational drivers behind suicidal ideation. Through qualitative analysis of individual cases, the research emphasizes the significance of familial and social dynamics, personality traits, and early-life traumas. **Results** indicate a critical need for integrated therapeutic approaches that address these complex interrelations to effectively reduce suicidal risk. Furthermore, the study advocates for enhanced access to psychotherapeutic services and the implementation of preventive measures tailored to the unique needs of individuals struggling with depression and associated disorders. Conclusions: the findings highlight the fundamental role of social, familial, and professional contexts in shaping suicidal motivation, alongside the significant impact of accentuated personality traits that precipitate suicidal ideation and behavior, emphasizing the need for comprehensive, individualized interventions that address both psychosocial and psychopathological dimensions. **Keywords**: DEPRESSION, SUICIDE, SUICIDAL IDEATION, ANXIETY, PERSONALITY DISORDERS, MENTAL HEALTH, PSYCHOPATHOLOGY, QUALITATIVE ANALYSIS, MOTIVATIONAL DRIVERS.

INTRODUCTION

Depression is one of the most common and severe mental disorders, affecting over 264 million people globally (1). Beyond impairing quality of life, it is a significant risk factor for suicide, the second leading

cause of death among young people. The relationship between depression and suicide is complex: while not all depressed individuals develop suicidal thoughts, various biological, psychological, social, and cultural risk factors increase vulnerability (2). Neurochemical imbalances involving serotonin and dopamine have been associated with depression, impulsivity, and suicidal behavior (3). Life experiences such as trauma, abuse, and social isolation, along with low self-esteem and negative self-perception, further intensify depressive symptoms (4-5). Social determinants, including socio-economic status, stigma, and lack of access to healthcare, exacerbate risk by limiting treatment-seeking (6).

Suicide accounts for about 700,000 deaths annually, and depression is one of its strongest predictors (7). Recent evidence shows rising suicide rates among adolescents and young adults (8), with particularly high risks in LGBTQ+ and marginalized groups (9). Nearly 60% of individuals who die by suicide suffer from mood disorders (10). Theoretical frameworks help explain these associations: cognitive theories emphasize distorted thinking and hopelessness (11); the Interpersonal Theory of Suicide highlights perceived burdensomeness and social disconnection (12); and the Diathesis-Stress Model underscores the interaction between genetic vulnerabilities and environmental stressors (13).

Comorbidity further complicates the picture. Anxiety disorders contribute to suicide risk by intensifying fear, stress reactivity, and difficulty coping with adverse events (14). Their frequent co-occurrence with depression amplifies vulnerability (15). Personality disorders, especially borderline and Cluster C types, increase risks through emotional instability, impulsivity, and problematic interpersonal relationships (16-17). Depression, anxiety, and personality disorders often interact cyclically, reinforcing each other and heightening suicidal behavior (18). This overlap necessitates integrated approaches that address multiple dimensions simultaneously.

Psychiatric patients are particularly vulnerable. Mental illness is associated with reduced life expectancy, often 15-20 years shorter than the general population, partly due to elevated suicide risk (19). Around 44% of suicide victims have a history of psychiatric hospitalization (20), with a 5% risk of self-harm during inpatient stays far higher than in the general population (21). Overall, affective disorders increase suicide risk 150-fold compared to individuals never hospitalized, while even outpatients face six to eight times higher risks than the general population (22-23). Thus, psychiatric care settings play a crucial role in prevention (24).

Demographic and socio-economic variables also influence suicide. In Western countries, higher risk is linked to male gender, advanced age, education, and employment status, with motivations including fears of financial loss, job insecurity, stigma, and illness progression (25). Stable predictors of suicide during hospitalization include depressive symptoms, affective or schizophrenia spectrum disorders, and prior self-harm (1). Additional risk factors include family history of suicide, hopelessness, guilt, and prolonged antidepressant use (27). However, suicide risk remains difficult to quantify due to fluctuating symptoms and impulsivity. Current prevention relies on better communication between clinicians, patients, and caregivers, along with comprehensive thera-

peutic interventions that address biological, psychological, and social dimensions of mental health.

OBJECTIVES

The aim of this study is to explore the peculiarities of suicidal ideation among hospitalized patients and those treated in outpatient psychiatric services. A comprehensive overview was developed to examine the correlation between suicidal risk and psychological, social, and biological characteristics, including clinical and syndromic features. The analysis focused on relative risk, trends, and socio-demographic and clinical factors in patients with non-organic depression. Demographic data and suicidal risk were compared across groups to identify specific vulnerabilities.

The main objective was to highlight pathophysiological and clinical perspectives that may support the development of practical preventive tools, while also examining each patient's declared suicidal motivation within the broader bio-psycho-social context. Beyond statistics, this study aims to humanize suicide in depression by describing psychopathological situations united by the desire to end life and the absence of reasons to continue. While the literature extensively addresses risk factors and predispositions, motivational aspects remain understudied despite their central role in suicidal behavior.

MATERIALS AND METHODS

This research presents 40 cases of patients with depressive episodes, either isolated or within recurrent major depressive disorder or bipolar affective disorder, with or without psychotic symptoms, all monitored between January 2022 and January 2024. Patients were almost equally distributed by gender and evaluated through psychiatric interviews, anamnesis, and psychological assessments, including Hamilton scales for depression and anxiety and a scale for accentuated personality traits, routinely applied at the Socola Psychiatric Institute in Iași. Data collected included personal and family history, socio-demographic conditions, and intrafamilial relationships, with results recorded in observation sheets. Both hospitalized and outpatient cases were analyzed, focusing on psychopathological indicators, suicidal risk, and declared motivations. For consistency, only patients with severe depressive or bipolar episodes, with or without psychotic symptoms and accompanied by suicidal ideation or attempt, were included.

Case structuring included the following components:

a) History of illness - reasons for hospitalization or psychiatric referral.

b) Hereditary background - psychiatric disorders and aberrant behaviors in relatives, with special focus on suicidal attempts in close family members.

c) Family background - relationships with family of origin and current family, communication patterns, and family situation at the time of the study.

d) Educational and religious background - behaviors related to education, confession, and relation to the divine.

e) Personal pathological history - somatic or psychiatric comorbidities, chronic pain, therapeutic adherence, and prior psychotropic treatment.

f) Living and working conditions - socio-professional status and psychosocial events acting as potential triggers of depressive episodes.

g) Psychiatric examination - psycho-

pathological elements (cognitive, volitional, affective functions), addictive behaviors, and declared suicidal motivation.

h) Psychological examination - scores from Hamilton scales (depression, anxiety) and the PA questionnaire (accentuated personality traits).

i) Positive diagnosis - established according to ICD-10 (International Classification of Disorders 10th edition), including type of suicidal behavior and secondary psychiatric diagnoses.

j) Therapeutic conduct - summarized treatment principles, medication classes, and combinations.

Ethical considerations: Informed consent was included in the standard agreement for hospitalization and therapeutic intervention. All patient data were anonymized.

RESULTS

Within the study group (N=40), patients diagnosed with depression spectrum disorders without associated personality disorders represented 55% (n=22), while those with comorbid personality disorders accounted for 45% (n=18), as illustrated in first figure.

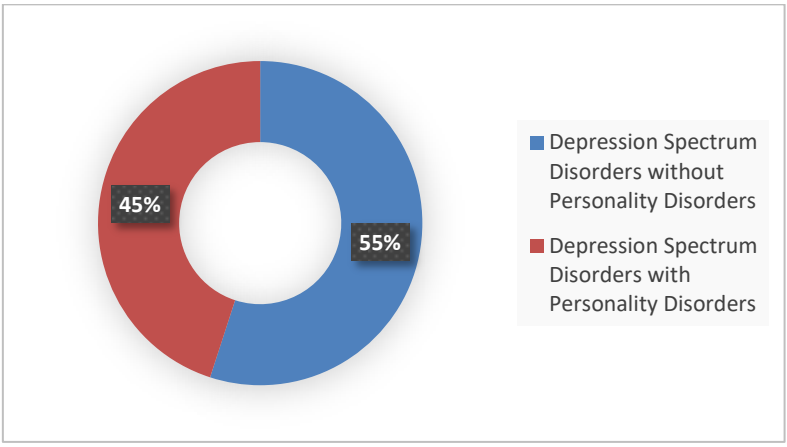

Fig. 1. Distribution of patients with depression spectrum disorders according to the presence of personality disorders.

In our cohort, patients with depression frequently presented with multiple personality disorders associated with an increased risk of suicide, as illustrated in second figure.

Distribution of personality disorders among patients with depression spectrum disorders. Borderline personality disorder was identified in 8 cases, avoidant personality disorder in 4 cases, and obsessive-compulsive personality disorder in 6 cases. These personality traits were variably associated with different forms of depressive episodes: borderline traits were most frequently observed in bipolar affective disorder with and without psychotic symptoms, avoidant traits appeared mainly in severe depressive episodes, while obsessive-compulsive traits were more frequent in major depressive disorder with psychotic symptoms. This distribution highlights the significant role of comorbid personality disorders in shaping suicidal risk in depressive spectrum disorders.

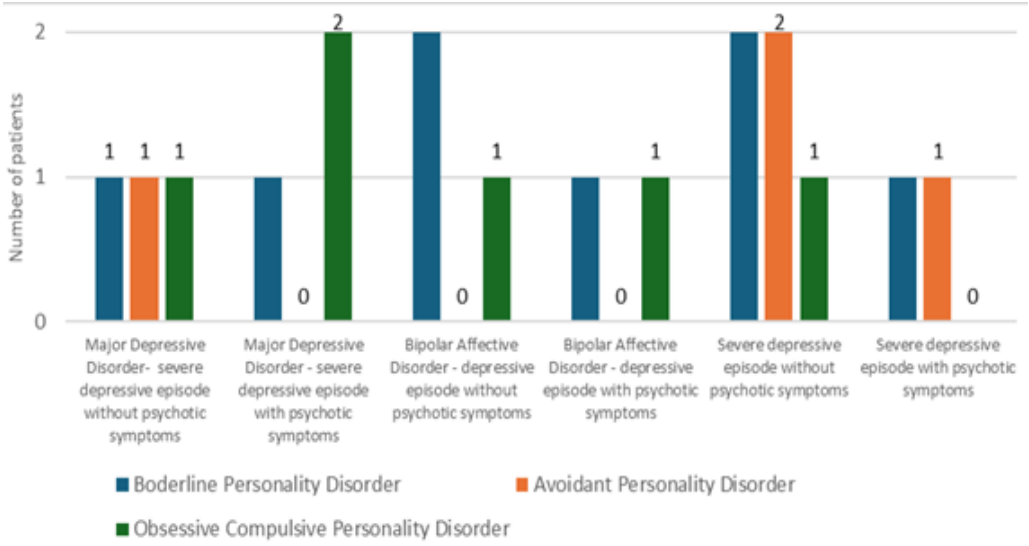

Fig. 2. Depression and Personality Disorders

The distribution of diagnostic categories within the study group (N=40) is shown in Figure 3. The largest subgroup consisted of patients with severe depressive episodes without psychotic symptoms (37.5%, n=15), followed by those with major depressive disorder, severe episode without psychotic symptoms (12.5%, n=5). Patients with major depressive disorder, severe episode with psychotic symptoms, and those with severe depressive episodes with psychotic symptoms each represented 7.5% (n=3). Bipolar disorder cases accounted for smaller proportions, with 5% (n=2) presenting with depressive episodes without psychotic symptoms and 5% (n=2) with depressive episodes with psychotic symptoms.

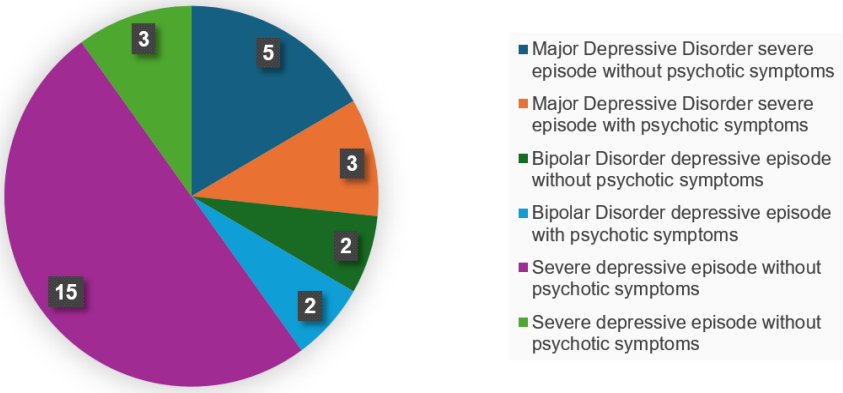

Fig. 3. Distribution of cases by diagnosis

Each case was assigned one primary suicidal motive: anxiety-intolerance (n=12), intense self-blame/guilt (n=14), socio-professional/family insertion problems related to childhood/adolescent trauma (n=18), and other mixed.

In the PD subgroup 10 out of 18 cases were coded with anxiety-intolerance *vs.* 2 out of 22 in the non-PD subgroup. Fisher exact test p = 0.006; Pearson $\chi^2(1) = 10.17$, $p \approx 0.0014$, indicating a statistically significant association. The estimated odds ratio (OR) for anxiety-intolerance in PD *vs.* non-PD = 12.5 (95% CI ≈ 2.23-70.3), showing substantially higher odds of anxiety-intolerance being the principal suicidal motive among patients with PD. the Pearson χ^2 gives consistent evidence of association when approximations are acceptable (fig. 4).

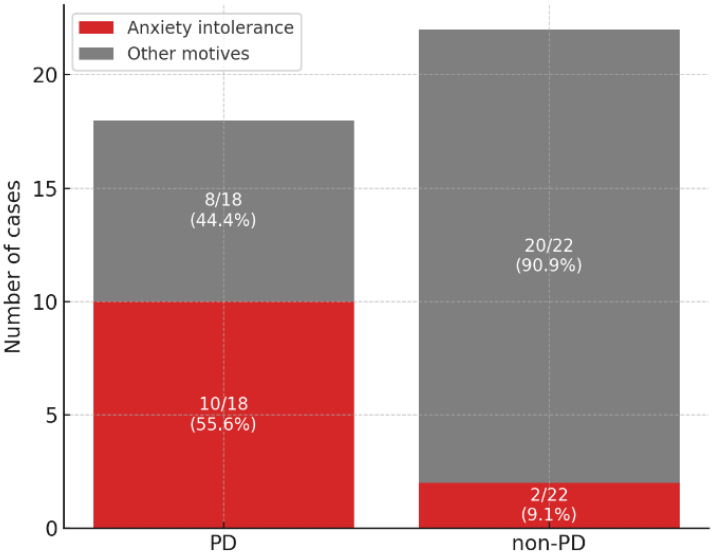

Fig. 4. Suicidal motives by PD status

Also, seven of the eight psychotic patients were coded as having intense self-blame as the primary motive versus 7 out of 32 among non-psychotic patients (psychotic: self-blame 7/other 1; non-psychotic: self-blame 7/other 25).

Fisher exact p < 0.001; Pearson $\chi^2(1) = 12.12$, $p \approx 0.0005$. OR (psychotic *vs.* non-psychotic) = 25.0 with 95% CI ≈ 2.62-237.7, indicating a very large point estimate but wide CI due to the small number of psychotic cases; the strong association is statistically robust but imprecisely estimated (fig. 5).

Socio-family motives were more frequent in the non-PD group: PD: socio-family 4/other 14 (18); non-PD: socio-family 14/other 8 (22). Fisher exact p = 0.002; Pearson χ^2 (1) = 6.86, $p \approx 0.0088$. OR for PD *vs.* non-PD ≈ 0.163 (non-PD *vs.* PD ≈ 6.13), 95% CI ≈ 0.040-0.671, indicating lower odds of socio-family motives in PD patients (or conversely higher odds in non-PD patients), with a CI that excludes unity but is moderately wide. Multiple comparisons: three primary hypothesis tests were adjusted (fig. 6).

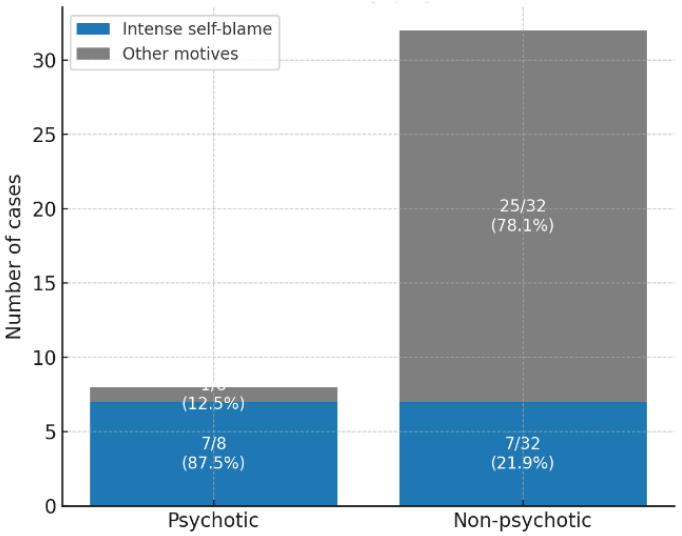

Fig. 5. Suicidal motives by psychotic status

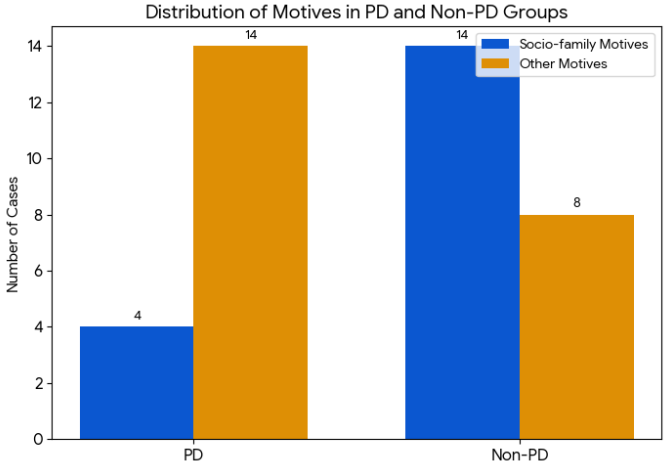

Fig. 6. Socio-family motives in PD and non-PD group

Bonferroni-corrected p-values (m = 3) are ≈ 0.0042 (anxiety-PD), 0.0015 (self-blame-psychotic), and 0.0264 (socio-family-PD) all remain below 0.05 after correction. Benjamin-Hochberg FDR ranks the p-values similarly (adjusted pBH ≈ 0.0015, 0.0021, 0.0088 respectively), so, the findings survive standard FDR control (fig. 7).

Sensitivity analyses (simulated reallocations) illustrate stability limits: moving two anxiety cases from PD to non-PD (PD 8/18 *vs.* non-PD 4/22) increases Fisher p ≈ 0.03 (association weakens and approaches the 0.05 threshold); reducing self-blame in the psychotic group by one case (6/8) yields Fisher p ≈ 0.0015 (association remains strong); moving two socio-family cases from non-PD to PD (non-PD 12/22, PD

6/18) yields Fisher p ≈ 0.015 (association weakens but remains below 0.05). Thus, the largest effect estimates (self-blame with psychosis; anxiety-PD) are robust to small reallocations, whereas the socio-family *vs.* PD association is more sensitive to case reclassification and has wider relative variability (fig. 8).

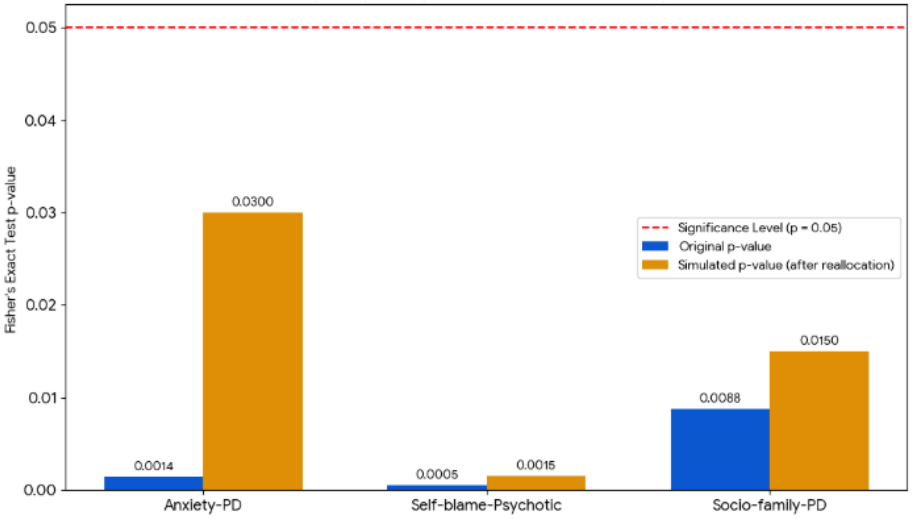

Fig. 8. Sensitivity analyses impact of cases on p-values

Data reported with contingency tables, Fisher and Pearson χ^2 tests, ORs and approximate 95% CIs, multiple comparison corrections and sensitivity checks-show strong, statistically significant associations of PD with anxiety-intolerance as the primary suicidal motive, of psychotic symptoms with intense self-blame, and a higher frequency of socio-professional / family motives in patients without PD; precision is limited for comparisons involving small cell counts (notably the psychotic subgroup).

DISCUSSION

Approximately 4-5% of patients hospitalized in psychiatric units present a suicide risk, which fluctuates over time due to multifactorial influences. The link between psychiatric disorders and suicidal behavior has been widely debated (1, 27), and therapeutic interviews can reveal the mosaic of ideations underlying such behavior. Suicide risk is heightened during clinical decompensation and shortly after hospital discharge, making predisposition to self-harm a frequent reason for hospitalization (2, 3, 27). Although the prevalence of in-hospital suicidal acts is low, some cases evade monitoring, highlighting the protective yet limited role of the hospital environment in restoring psychosocial-emotional balance.

Diagnoses were established according to ICD-10, with descriptive extensions capturing ideation, rumination, self-harming attempts, and clinically significant anxiety. The Hamilton scales for depression (21-items version) and anxiety, alongside the PA questionnaire (Accentuated Personality Traits Questionnaire), assessed accentuated personality traits, including emotional instability, impulsivity, hyperthymia, cyclothymia, dysthymia, anxiety,

and demonstrativeness, to explore correlations with depression and suicidal behavior (2, 4, 27).

Organic pathologies and certain psychiatric comorbidities (Axis I disorder except anxiety spectrum, cognitive deficits, dementia, or active addictive syndromes) were excluded, while cases with mild personality disorders or accentuated traits were included (5-6).

Cases were presented descriptively to explore familial, social, and psychological dimensions, aiming to identify correlations between multiple life domains and suicidal motivation (15, 16). Therapeutic schemes effective in the short- and medium-term, including guideline-approved and off-label medications, were documented (7). Antidepressants were often combined with antipsychotics such as Olanzapine or Quetiapine, providing both symptom control and mood stabilization for depressive or bipolar episodes (12). Medication doses were tailored to each patient's clinical context and semiological characteristics, with minimal effective doses prioritized.

Suicidal ideation emerged variably, influenced by social, familial, or professional integration, early-life traumas, psych genealogical patterns, or psychotic symptoms, but consistently tied to a diminished or absent motivation to live. In some cases, religious values acted as protective factors, while psychotic depression involved delusional or hallucinatory motivations for self-harm. Accentuated personality traits, impulsivity, and emotionality, often combined with relational problems or family history of aggression or suicide, contributed to vulnerability (8, 9). Low or fluctuating self-esteem was a constant factor throughout patients' lives (fig. 9).

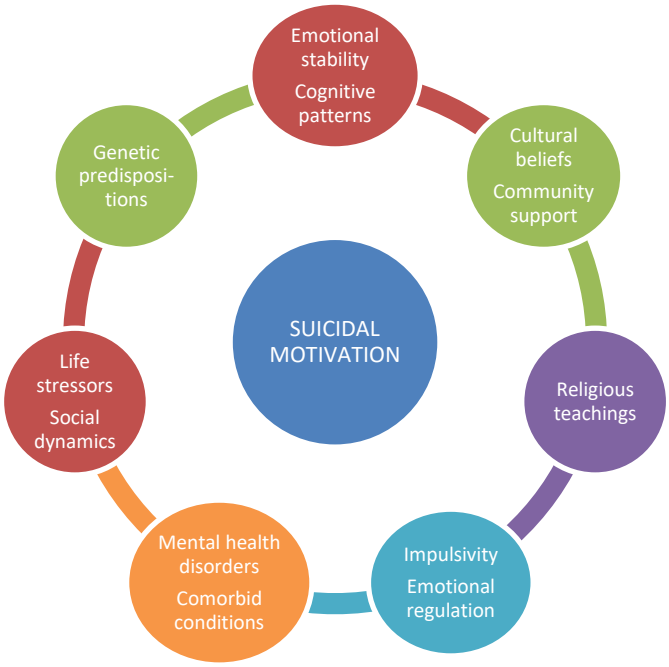

Fig. 9. Factors that Influence Suicidal Motivation

Qualitative analysis indicated that suicidal behavior results from the interaction of socio-familial, educational, psychological, and biological factors, raising questions about neuroplasticity and neuromodulation (10-11). Pharmacological treatment focused on alleviating depressive symptoms and eliminating suicidal ideation, usually combining antidepressants with antipsychotics for both therapeutic and preventive effects (12-14). A significant limitation in suicide management in the country is limited access to psychotherapeutic services, which can provide deeper insights into the individual motivational drivers of suicidal behavior (13).

CONCLUSIONS

In conclusion, the findings highlight the fundamental role of social, familial, and professional contexts in shaping suicidal motivation, alongside the significant impact of accentuated personality traits that precipitate suicidal ideation and behavior. Across individual cases, patterns of psychotic symptomatology further increase suicidal risk, sometimes serving as the primary driver for self-harming actions or persistent planning of such acts. Importantly, whether occurring in isolated depressive episodes or within major depressive or bipolar disorders, suicidal ideation consistently reflects an absence of motivation to live, rooted in early developmental stages. Once the motivation to live diminishes, the drive to suppress one's existence emerges, emphasizing the need for comprehensive, individualized interventions that address both psychosocial and psychopathological dimensions.

CONFLICT OF INTERESTS

The authors declare that there is no conflict of interests.

ANALYSIS OF RISK FACTORS FOR NEUROLOGICAL COMPLICATIONS OF SARS-COV-2 INFECTION: FOCUS ON CHRONIC FATIGABILITY (Abstract): **Aim:** Chronic fatigue syndrome is a long-term neurological manifestation that significantly affects the quality of life of patients. Its etiology is incompletely known, although it can occur after various infections including COVID-19, and the associated risk factors are not fully defined. The aim of the current study was to evaluate neurological manifestations in long-COVID and to identify potential risk factors for these complications. **Materials and methods:** We performed retro - prospective study on patients with history of COVID-19 infections. Patients were assessed up to 3 years after infection. Clinical and neurological investigations, brain imaging, analysis of inflammatory markers, levels of vitamin B_{12}, folic acid and vitamin D were carried out. Neurocognitive status was assessed using a validated semiquantitative scale. **Results:** In 132 eligible patients, 41.67% of cases developed chronic fatigability. Other neurological manifestations associated with Long-COVID were dizziness (29.17% cases), and memory impairment (25% cases). The deterioration of the neurocognitive status 1 year after infection was significantly correlated with the patient's age ($p<0,0001$), serum vitamin D ($p=0.015$), as well as vitamin B12 ($p=0.006$). **Conclusions:** Chronic fatigability is a common neurological complication of COVID-19 infection. Older people, those with low vitamin D and vitamin B12 levels, have higher risk of developing this syndrome. The COVID-19 infected patients need multiple investigations and a multidisciplinary approach to prevent these long-term complications. **Keywords:** RISK FACTORS, NEUROLOGICAL COMPLICATIONS, SARS-COV-2, INFECTION, FATIGABILITY.

INTRODUCTION

More than three years after the COVID-19 pandemic began, accumulating evidence highlights how SARS-CoV-2 infection has impacted patients' quality of life. Initially, it was considered that the new coronavirus had only respiratory tropism; however, later real - world data showed that it produces a wide range of symptoms, including neurological ones. Moreover, the persistent complications following SARS-Cov-2 infection are extremely varied. For this reason, a series of clinical manifestations have been correlated with the infection and classified as the Long–COVID complication.

In fact, several forms of post-COVID-

19 complications have been identified and defined so far and included in this umbrella term of Post COVID-19 conditions (1). Center for Disease Control and Prevention (CDC) defines this complication as Long COVID that "include a wide range of ongoing symptoms and conditions that can last weeks, months, or even years". According to the CDC, the symptoms of Long COVID should be improved within 3 – 6 months (2).

The World Health Organization (WHO) later provided a definition for Post COVID-19 condition, describing it as "the continuation or development of new symptoms three months after the initial SARS-CoV-2 infection, with these symptoms lasting for at least two months and with no other explanation" (3).

Clinical sequelae of COVID-19 include respiratory (lung fibrosis), cardiovascular (thrombosis, myocarditis, arrhythmias), metabolic (diabetes), dermatologic (alopecia), renal, and neurological complications (4). Neurological manifestations of Long COVID include fatigue, "brain fog," sleep disturbances, mood disorders, cognitive dysfunction, anxiety, depression, and stroke (5). Their prevalence is uncertain but may reach 50% worldwide. Reported risk factors described in other studies include female sex, comorbidities, lack of COVID vaccination, obesity (increased) BMI, with women more frequently experiencing headache, stress, concentration difficulties, and fatigue (6).

In this context, we conducted a retro-prospective study to evaluate neurological manifestations of Long COVID and potential risk factors.

MATERIALS AND METHODS

We performed a retro-prospective study which included patients with history of SARS-CoV-2 infections. Patients were hospitalized and evaluated in Sf. Parascheva Clinical Hospital of Infectious Diseases Iasi and Equilibrium Clinic between 2021-2024.

The study was approved by the Ethics Committee of the hospital, the Ethics Committee of the Grigore T. Popa University of Medicine and Pharmacy Iasi. The data was collected in agreement to ensure data protection. The informed consent was obtained from the patients or their legal representatives before the inclusion in the study.

Eligible patients met the criteria: written informed consent obtained from the patient or their legal representative, patients aged over 18 years with history of SARS-CoV2 infection, patients evaluated up to 3 years after COVID-19 infection. Patients with history of chronic fatigue syndrome before COVID-19 infection or with incomplete data were excluded.

Data collection. Data collected from medical records included demographics (age, sex), medical and medication history, SARS-CoV-2 infection details (severity, reinfections, treatment, outcome), laboratory findings (complete blood count, biochemistry, inflammatory markers, serum vitamin D, folic acid, vitamin B_{12}), neurological evaluation, and cerebral CT. Neurological status was assessed with the extended SCGI scale, covering cognition, affective state, sleep, fatigue, headache, motor and sensory function, balance and coordination, functional autonomy, and quality of life. Each domain was scored 0–3, with total scores categorized as mild (0–10), moderate (11–20), or severe (21–30). This is an interim analysis of data obtained one year after infection. Therefore, only

data up to this time point have been collected and analyzed.

Statistical analysis. Normally distributed data are presented as means ± standard deviations, and nonnormally distributed data are reported as medians and ranges). The chi-squared test was performed for the single-factor analysis of count data, and the Kruskal-Wallis was performed for the single-factor analysis of non-normally distributed data. Pearson correlation coefficients were used for correlation between different variables. A p-value ≤0.05 was considered statistically significant. Statistical analysis was performed using XLSTAT software version 1.3, 2025 (Lumivero, USA).

RESULTS

Of a total of 183 patients, 132 eligible cases were included in our analysis. Of these, 41.67% cases were males. The mean (St. dev.) age was 49.43 (±18.98) years in females and 57 (±15.51) years in males (fig. 1).

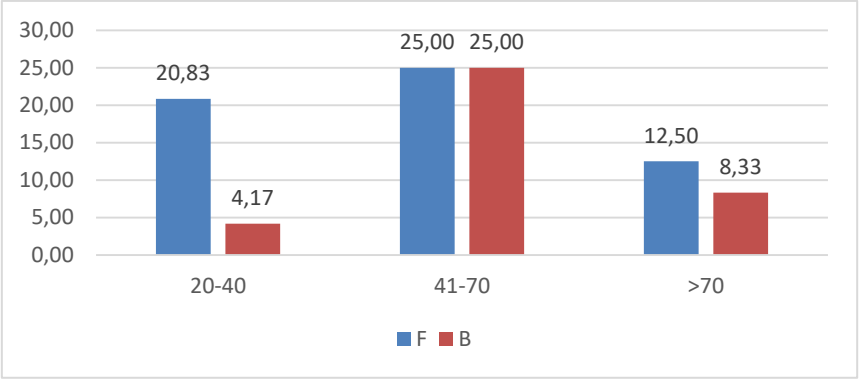

Fig. 1. Demographic data - gender repartition by age group (%)

Almost 67% of cases described associated disorders, most of them with negative prognostic impact associated with COVID-19 infection (hypertension, metabolic disorders, hematological diseases).

The neurological manifestations recorded up to 1 years after SARS-CoV-2 infection in the patients surveyed were varied: paresthesia, nonspecific myalgias or fibromyalgia, headache or migraine, various neuralgias (trigeminal, facial), confusional syndromes or new or aggravated cognitive disorders in patients with previous cognitive impairment (with MMSE score 18-20). However, the most frequent neurological disorder was chronic fatigue syndrome reported in all age groups (41.67% of cases) (fig. 2).

The 55 patients with chronic fatigue syndrome were subsequently analyzed to establish correlations between demographic and biological parameters with the degree of neurocognitive impairment (SCGI Scale) (tab. I, fig. 3).

The data obtained revealed a significant correlation between the severity of cognitive impairment (SCGI score between 27-30) and the patient's age ($p<0,0001$). A weaker, but clinically significant correlation was also obtained for serum vitamin D values ($p=0.015$), as well as for vitamin B_{12} ($p=0.006$). Patients' gender was not correlated with neurological manifestations in our analysis ($p=0.589$).

DISCUSSION

The SARS-CoV-2 virus is responsible for a multisystem infection, and neurological manifestations are common in the acute phase of infection. Multiple clinical studies, as well as real-world clinical experience, have shown that symptoms such as headaches, anosmia, ageusia, paresthesia, and myalgias are significant in COVID-19. A retrospective analysis of patients admitted to the "Sf. Parascheva" Infectious Diseases Hospital in Iasi between 2020 and 2022 showed that the most common symptoms were fatigue (85% cases), headache (51.25% cases), myalgia (41.25% cases) (7). To date, various hypotheses have been proposed regarding the pathophysiological mechanisms of neurological disorders in COVID-19, including direct invasion of the central nervous system, disruption of the blood-brain barrier, or dysregulation of the gut–brain axis (5).

On the other hand, the SARS-CoV-2 virus can trigger a "cytokine storm," characterized by the excessive release of pro-inflammatory cytokines (TNF-alpha, IL-6, IL-1, etc.), with significant changes in the immune system that ultimately lead to a systemic hyperinflammation syndrome (8). This mechanism can also induce neuroinflammation, which is responsible for both acute symptoms and long-term neurological changes (5, 8, 17).

Analysis of a cohort of over 150,000 patients in the USA identified the following neurological complications of SARS-CoV-2 infection, classified as Long-COVID syndrome: cerebrovascular diseases, cognitive and memory disorders, peripheral nerve disorders, migraine, extrapyramidal and motor disorders psychiatric disorders, and other complications (dizziness, drowsiness, Guillain–Barré syndrome, encephalitis, transverse myelitis, encephalopathy) (9-11). Our data are in line with extensive studies published by other authors. The most common neurological manifestations were chronic fatigue syndrome (over 40% of cases), followed by cognitive deficit with new onset or worsening of a pre-existing cognitive deficit.

Chronic fatigue syndrome defined as Myalgic Encephalomyelitis is a complex condition, characterized by significant asthenia, reduced exercise capacity, cognitive disorders (including "brain fog"), sleep disorders, myalgia or other forms of pain, vegetative syndrome (12). The etiology is not completely known, but a prevalence of up to 11% has been identified in severe infections (Epstein Barr virus (EBV), Ross River virus, Giardia lamblia, parvovirus B19, and Q fever infections) (13).

In an extensive analysis of 41,802 women in the US, chronic fatigue syndrome was identified in only 102 women. Risk and predisposing factors for Myalgic Encephalomyelitis or severe fatigue were advanced age, higher BMI in adulthood, hormone therapy, alcohol intake (14). In our study, patients' age, as well as serum levels of vitamin D and vitamin B_{12}, were significantly correlated with the occurrence of chronic fatigue.

The protective role of vitamin D in infectious pathology has been intensively studied and is well defined. In addition to its direct involvement in calcium metabolism and the maintenance of bone health, vitamin D exerts numerous effects, including anti-inflammatory, immunomodulato-

ry, and even antibacterial or antiviral properties (15). Increasing amounts of data are available regarding the relationship between vitamin D and cognitive function. Vitamin D receptors have been identified in the nervous system (neurons and glial cells). Vitamin D has been found to impact numerous brain processes, including cell differentiation, neurotrophic factor production and release, neurotransmitter synthesis, intracellular calcium homeostasis, prevention of oxidative damage, neuronal structure and metabolism, and ultimately, cognitive functioning (16). Hypovitaminosis D has been associated with the onset of neurodegenerative diseases, schizophrenia (18). Clinical data support this benefit of vitamin D for the treatment of several neurocognitive disorders, including those associated with chronic fatigability.

The small sample size evaluated is the main limitation of the current analysis. However, this is an interim analysis of patients monitored up to three years and the final conclusions will be disseminated.

CONCLUSIONS

Chronic fatigability is a common neurological complication of COVID-19 infection. Older people, those with low vitamin D and vitamin B_{12} levels, have higher risk of developing this syndrome.

The COVID-19 infected patients need multiple investigations and a multidisciplinary approach to prevent these long-term complications.

BASELINE PREDICTORS OF ONE-YEAR DISEASE-RELATED MORBIDITY IN PATIENTS WITH NEWLY DIAGNOSED ULCERATIVE COLITIS (Abstract): Early identification of factors predicting disease course in ulcerative colitis (UC) is essential for guiding therapeutic decisions and improving patient outcomes. Recognizing patients at higher risk of unfavorable evolution allows closer monitoring and timely treatment escalation. Clinical severity, disease extent, biochemical abnormalities, and concomitant infections may all influence prognosis. Among these, *Clostridioides difficile* infection (CDI) is increasingly recognized in UC, although its independent impact on disease course remains uncertain. **Aim:** To assess baseline clinical and biochemical severity markers, as well as concomitant CDI at diagnosis, as predictors of disease-related morbidity during the first year following UC diagnosis. **Materials and methods:** We conducted a retrospective study including 125 patients newly diagnosed with UC and followed for at least 12 months. Collected data included demographic characteristics, clinical presentation, biochemical markers, endoscopic findings, and the presence of CDI at diagnosis. Disease-related morbidity was defined as any UC-related hospitalization occurring within the first year after diagnosis, excluding the initial diagnostic admission. Statistical analysis comprised bivariate testing and multivariate logistic regression to identify independent predictors of hospitalization. **Results:** Independent predictors of UC-related hospitalization were Mayo clinical score (OR=1.28; 95% CI 1.00-1.64; p=0.043), pancolitis (OR=3.45; 95% CI 1.35-8.79; p=0.009), and hypoalbuminemia (OR=3.73; 95% CI 1.09-12.71; p=0.035). CDI was present in 20% of patients but did not independently predict hospitalization (OR=1.84; p=0.265). **Conclusions:** Baseline clinical activity, disease extent, and hypoalbuminemia are independent predictors of early UC-related morbidity. These findings underscore the importance of comprehensive initial assessment to support early risk stratification and individualized management strategies. **Keywords:** ULCERATIVE COLITIS, DISEASE-RELATED MORBIDITY, HOSPITALIZATION, BASELINE PREDICTORS.

INTRODUCTION

Ulcerative colitis (UC) is a chronic condition characterized by mucosal inflammation, characterized by a relapsing - remitting course. It typically begins in the rectum and extends proximally throughout the colon in a continuous manner.

During the past decades, the incidence

of inflammatory bowel disease (IBD) has increased, especially in developing countries. Immune system dysfunction and intestinal microbiome imbalance, along with the influence of environmental factors on genetically predisposed individuals, are the main mechanisms involved in the development of ulcerative colitis. Currently, the treatment of ulcerative colitis relies on corticosteroids for acute flares, amino salicylates, conventional immunosuppressants, and targeted biologic or small-molecule agents (1).

Therapeutic goals in IBD have recently evolved into a structured framework of short-term, intermediate and long-term targets, as outlined in the STRIDE-II consensus (2).

Short-term targets include symptomatic relief and normalization of C-reactive protein (CRP) as a general inflammatory marker, intermediate targets focus on decrease of fecal calprotectin, while long-term goals aim for achieving endoscopic healing, improved quality of life, and prevention of disease-related complications, disability and surgery. While not formally defined as treatment target, transmural healing in Crohn's disease and histological healing in UC are recognized as valuable therapeutic milestones (2). The lack of histological inflammation is linked to decreased relapse rates, as well as fewer hospital admissions, surgical interventions, and lower risk of neoplastic complications (3).

Accordingly, current strategies emphasize individualized care and close monitoring to guide therapy optimization. Furthermore, the early identification of factors that predict disease course in ulcerative colitis is essential to guide therapeutic decisions and improve patient outcomes. Timely recognition, ideally at diagnosis, of patients at higher risk of unfavorable evolution allows for more intensive monitoring and appropriate escalation of therapy within the "window of opportunity".

Certain baseline parameters, including clinical and laboratory characteristics, disease phenotype, laboratory findings, and histological grading have been associated with poor prognosis (4). Additionally, superimposed infections such as *Clostridioides difficile* may further complicate the clinical course.

The aim of our study was to identify baseline predictors of unfavorable disease progression, with a specific focus on early relapse during the first year after diagnosis.

MATERIALS AND METHODS

Study design and patients. We conducted a retrospective observational study including 125 consecutive patients newly diagnosed with UC who were followed for at least 12 months after diagnosis.

Patients were eligible for inclusion if they were newly diagnosed with UC based on clinical, endoscopic, and histologic criteria, and had at least 12 months of documented follow-up. Exclusion criteria were: previous total or subtotal colectomy, unconfirmed diagnosis, missing key data regarding *Clostridioides difficile* testing, endoscopic or histologic assessment, or loss to follow-up before completing the 12-months monitoring period.

The primary endpoint of our study was one-year disease-related morbidity, defined as any UC-related hospitalization occurring in the first year after diagnosis, including admissions due to disease flares or UC-related complications. Hospitalizations unrelated to UC were excluded from the analysis.

Data collection. Clinical, demographic, biochemical, endoscopic, and histologic data were collected from electronic medical records at the time of diagnosis. Disease severity and extent were assessed using the Mayo clinical score, Mayo endoscopic sub score, and the Montreal classification. All hospitalizations occurring within the first 12 months following baseline presentation were reviewed for each patient using the institutional electronic medical database.

Statistical analysis. Descriptive statistics were used to summarize baseline characteristics. Between-group comparisons were performed using the Mann-Whitney U test for continuous variables and the Chi-square test for categorical variables. Variables with a p-value <0.1 in univariate analysis were entered into a multivariate logistic regression model to identify independent predictors of UC-related hospitalization. Results were expressed as odds ratios (OR) with corresponding 95% confidence intervals (CI). A two-tailed p-value <0.05 was considered statistically significant. Analyses were performed using IBM *SPSS Statistics*, version 26 (IBM Corp., Armonk, NY, USA).

RESULTS

Patients' characteristics and one-year UC-related morbidity rate

A total of 125 patients with newly diagnosed UC were included in the study. The median age at diagnosis was 39 years (interquartile range [IQR] 26-49), and 54,4% were male. Extensive colitis (E3) was present in 36,5% of patients. The baseline demographic, clinical, and laboratory characteristics of patients are summarized in first table.

During the first year after diagnosis, 40 patients required UC-related hospitalization, predominantly for disease flares, corresponding to a 1-year morbidity rate of 32%.

Predictive factors for one-year UC-related morbidity

The correlations between baseline clinical, biological and endoscopic parameters and the risk of hospitalization were assessed by univariate and multivariate models. Results of the univariate analysis are presented in second table.

Fecal calprotectin µg/g	687 (299-1489)	857 (347-2232)	0.255
MES 3, n (%)	26 (53%)	23 (47%)	0.004*

Patients who were hospitalized within the first year had significantly higher baseline Mayo scores (p=0.002), lower hemoglobin (p=0.010), lower serum albumin (p=0.001), and higher CRP levels (p=0.026). Hospitalization was also more frequent among male patients (p=0.016), those with extensive colitis (E3) (p < 0.001), and patients with *Clostridioides difficile* infection (CDI) at diagnosis (p=0.017).

The Mayo endoscopic sub score was strongly associated with hospitalization risk (*p*=0.004), with more severe endoscopic activity corresponding to increased morbidity rates.

Multivariate logistic regression identified the following independent baseline predictors of one-year hospitalization (tab. III): higher Mayo clinical score (OR=1.28; 95% CI 1.00-1.64; p=0.043), extensive colitis (OR=3.45; 95% CI 1.35-8.79; p=0.009) and hypoalbuminemia (OR=3.73; 95% CI 1.09-12.71; p=0.035).

Although gender, hemoglobin levels and CDI status were associated with hospitalization in univariate analysis, they did not retain independent significance in the multivariate model (p > 0.05). Interestingly, C-reactive protein showed an inverse association with hospitalization risk (OR=0.86; 95% CI 0.77-0.97; p=0.015), likely reflecting the influence of extreme CRP elevations observed in patients with concomitant *C. difficile* infection.

A sub analysis comparing CRP levels between CDI-positive and CDI-negative patients at diagnosis revealed higher inflammatory activity among CDI-positive patients (median 1.74 mg/dL vs 0.98 mg/dL; p=0.055) (tab. IV).

TABLE III.

Independent predictive factors for hospitalization - multivariate analysis

Variable	B	P	Exp (B)	95% C.I for Exp (B)	
				Lower	Upper
Mayo score	0.25	0.043	1.28	1.00	1.64
CRP	-0.14	0.015	0.86	0.77	0.97
Hypoalbuminemia (< 3,5 g/dL)	1.31	0.035	3.73	1.09	12.71
Extension (E3)	1.23	0.009	3.45	1.35	8.79
CDI at diagnosis	-0.27	0.608	0.75	0.26	2.19
Gender	0.91	0.063	2.50	0.95	6.57
Hemoglobin	-0.14	0.287	0.86	0.67	1.12

TABLE IV.

Correlation between CRP levels in CDI positive and negative patients at diagnosis

Variable	CDI positive	CDI negative	p-value
C-reactive protein mg/dL, Median (IQR)	1.74 (0.87-6.11)	0.98 (0.33-3.42)	0.055

DISCUSSION

Demographic and clinical characteristics such as age, gender and disease phenotype at onset have been explored as potential prognostic indicators in UC. The impact of age remains debated. Unlike Crohn's disease, the Montreal classification for UC does not include age at diagnosis as a defining parameter, owing to inconsistent findings across studies. Some reports associate younger age, female sex, and extraintestinal manifestations with higher relapse rates, whereas others link male sex and extensive colonic involvement with an increased risk of colectomy (5-7). In our study no correlation between group age and gender was noted.

Clinical and laboratory markers reflecting high disease activity at diagnosis are key prognostic determinants in UC. Stratifying disease severity is crucial for guiding treatment decisions and anticipating disease progression. A combination of clinical, biological and endoscopic indicators provides valuable prognostic information. Features as persistent fever, frequent bloody stools, elevated inflammatory markers, and low serum albumin levels have been consistently associated with poor response to therapy and higher colectomy rates (4). Among biological markers, CRP remains a widely used and accessible inflammatory biomarker. Elevated CRP at diagnosis is associated with more extended disease and an increased risk of colectomy. Persistently high CRP levels during follow-up are also correlated with worse outcomes, regardless of treatment, highlighting its value as a surrogate for disease burden and prognosis (8).

In our analysis, a higher Mayo score - incorporating both clinical and endoscopic activity, was an independent predictor of UC-related hospitalization during the first year. These findings confirm the Mayo score's prognostic utility beyond activity assessment, suggesting that greater baseline disease severity translates into a higher morbidity burden over time.

Although CRP and fecal calprotectin are established inflammatory markers, they were not independently associated with one-year morbidity in our cohort. This may reflect their limited prognostic value once acute inflammation diminishes after treatment initiation. They primarily indicate inflammatory burden at diagnosis but do not necessarily predict mid-term outcomes in newly diagnosed patients.

Disease extent is another well-recognized prognostic factor. Patients with extensive colitis typically experience a more aggressive disease course, are more likely to require immunosuppressive or biologic therapy, and have lower response rates to amino salicylates (4). In our cohort, extensive colitis emerged as an independent predictor of UC-related hospitalization (OR=3.45; p=0.009), emphasizing the importance of accurately determining disease extent at baseline, ideally by colonoscopy and, when needed, supported by cross-sectional imaging.

Serum albumin is classified as a negative acute phase reactant, and its levels tend to decrease in the presence of inflammation. In UC, hypoalbuminemia results from increased catabolism and protein loss through the inflamed mucosa, while additional factors such as malnutrition and malabsorption further contribute to decreased levels (9). Previous studies have identified hypoalbuminemia as a strong predictor of poor outcomes, including treatment failure, colectomy,

and non-response to thiopurines or anti-TNF therapy (9,10). In line with these findings, our study demonstrated that hypoalbuminemia is associated with an increased risk of hospitalization in the first year after diagnosis (OR=3.73; p=0.035). These results underscore the prognostic value of albumin as a simple, cost-effective marker for early risk stratification in UC.

The impact of CDI in UC remains controversial. CDI occurs more frequently during UC flares and has been linked to worse short- and medium-term outcomes, including increased healthcare costs, longer hospital stays, higher colectomy rates, and more frequent hospital visits (8). However, data are conflicting. Some studies reported increased colectomy and mortality in CDI-positive UC patients (11, 12), while others found no significant long-term impact (13, 14). In our cohort, CDI at diagnosis was associated with higher CRP levels, indicating greater inflammatory activity, but did not independently predict one-year hospitalization. These findings support the hypothesis that CDI may exacerbate inflammation or unmask preexisting mucosal disease without directly worsening long-term prognosis.

Interestingly, 20% of our patients were diagnosed with UC in the context of CDI, suggesting that infection may act as a trigger in genetically or immunologically susceptible individuals.

Several limitations should be acknowledged. The retrospective, single-center design limits causal inference. The relatively small number of CDI-positive patients may reduce statistical power to detect differences in some outcomes. Additionally, although hospitalization was used as an objective marker of morbidity, we did not perform subgroup analyses based on the cause of admissions (e.g., flare vs. complication), which may have limited specificity. Moreover, using hospitalization as a marker of morbidity may overlook important aspects such as health-related quality of life or outpatient care requirements.

CONCLUSIONS

This study identified a higher Mayo clinical score, extensive colitis, and hypoalbuminemia as independent baseline predictors of UC-related hospitalizations within the first year after diagnosis. These findings highlight the importance of a comprehensive initial assessment, integrating clinical, biochemical, and endoscopic parameters to improve early risk stratification and guide timely, individualized treatment decisions.

Clostridioides difficile infection was associated with more pronounced biochemical inflammation, but it did not independently predict one-year morbidity. This suggests that CDI may exacerbate mucosal inflammation or unmask underlying disease rather than directly worsening mid-term outcomes.

From a clinical perspective, patients presenting at diagnosis with extensive colonic involvement, elevated Mayo score, and low albumin levels may benefit from closer surveillance and timely therapeutic escalation.

THE ETIOPATHOGENETIC PATHWAYS CONNECTING PSORIASIS AND MENTAL HEALTH DISORDERS (Abstract): Psoriasis is a chronic immune-mediated skin condition that goes beyond the cutaneous symptoms, often affecting patients' mental health and social interactions. Psychiatric comorbidities like depression, anxiety, and sleep disorders are prevalent and can be worsened by stigma and discrimination. The psychology of psoriasis is discussed in this article based on a 2023 study that used a questionnaire to investigate discrimination, treatment expectations, sleep, and perceived psychosocial effects of psoriasis. **Materials and methods**: A questionnaire of 101 questions was given to psoriasis patients via social media (n = 155). The responses were assessed descriptively and using multivariable regression. Correlations between discrimination, sleep disturbances, expectations, and side effects on family life, work, and relationships were the focus of the study. **Results**: Almost half of the participants (43.2%) had experienced discrimination or stigma. Discrimination was strongly related to self-reported negative effects on family life (52.3%), work performance (49.0%), and interpersonal relationships (54.2%), with a moderate effect size (χ^2 = 32.26, $p < 0.001$). Sleep issues were less frequently reported (6.5%) and were not strongly related to discrimination. **Conclusions**: Psoriasis is inextricably linked with mental health, not just a cause of biological inflammation but also social stressors such as stigmatization. The results identify the fact that discrimination plays an underlying part in reducing quality of life, and problems with sleep may be less centrally involved. An integrated medical, psychological, and social treatment approach is needed for overall treatment. **Keywords:** PSORIASIS, PATHOLOGY, MENTAL DISORDERS, HEALTH.

INTRODUCTION

Psoriasis is more than a skin disease; it is an inflammatory condition with strong psychological and social consequences. Although scientific research has mainly targeted immune processes and treatment (1), mounting evidence illustrates the substantial psychosocial burden, such as stigma and discrimination, and their adverse impact on mental health (2, 3). In a previous questionnaire-based study on psoriasis, the necessity of approaching this topic from a new perspective was brought up, linking psoriasis to different comorbidities, interrelationships

and its multifactorial factors was taken more seriously (4). Patients must often contend with a double burden: visible lesions that garner unwanted attention and inner turmoil that is not observable, including shame and a changed self-image (5). Comorbid depression, anxiety, and sleep disorders are prevalent, which puts psoriasis in the realm of mind-body medicine, in which psychological and physical components cannot be separated (6, 7).

Stigma also plays a significant role in increasing emotional vulnerability through social rejection and internalization of negative beliefs that decrease self-worth and hope (2, 3). Discrimination, sleep disturbances, and expectations about treatment and their impact on everyday life and mental health are reviewed here, emphasizing the necessity for comprehensive care addressing physical as well as psychosocial domains. With the pioneering research of Wittkower in the 1940s connecting psoriasis with emotional stress (8), studies have explained complex bidirectional associations among psoriasis and psychiatric illness. Stress disrupts the hypothalamic–pituitary–adrenal axis and the sympathetic-adrenal-medullary system, resulting in chronic systemic inflammation (9).

Improved cytokine secretion by cytokines such as TNF-α and IL-6 plays a role in psoriatic skin lesions and also psychiatric illnesses such as depression, thereby providing a two-way link between inflammation and distress (10, 11). Other psychosocial elements such as stigma, inefficient coping mechanisms, alexithymia, and discrimination could augment the burden of disease regardless of lesion severity (2, 3).

Understanding these entangled biological and psychosocial processes presented in first figure is essential for the creation of multicomponent treatments that address both dermatological symptoms and mental health, along with social functioning.

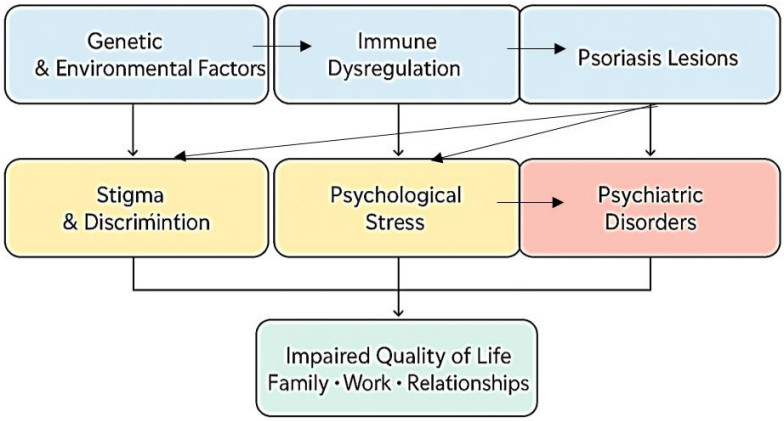

Fig. 1. Etiopathogenetic Pathways Connecting Psoriasis and Mental Health Disorders

MATERIALS AND METHODS

A structured, 101-question survey was developed to collect sociodemographic information, clinical history, and psychosocial results of the patients with psoriasis. The survey was sent in 2023 to a sample of individuals with psoriasis via social media (n = 155). Because the questionnaire was distrib-

uted primarily through psoriasis forums, the sample may be subject to selection bias, potentially overrepresenting individuals who are more engaged in online patient communities. Questions addressed areas like perceived discrimination, insomnia or sleep disruption, expectations from treatment, and family, occupational, and interpersonal relationship impacts of psoriasis.

Descriptive statistics were calculated for all responses. Discrimination and psychosocial variables' cross-tabulations were tested using Pearson's chi-square test and Cramer's V to establish the effect size. Multivariable logistic regression was performed with discrimination (yes/no) as the outcome variable, predictors such as age, sex, insomnia, and expectation categories.

The Declaration of Helsinki was followed in the conduct of the study. Each participant received information about their rights regarding data protection and how their personal data was processed in accordance with Regulation (EU) 2016/679 (GDPR) and any applicable national laws. Each participant provided written informed permission attesting to their knowledge of data protection.

RESULTS

One hundred fifty-five questionnaires were completed and returned. Respondents' average age was 39 years, ranging from 18 to 73 years, 79% of them were female and 21% male.

Discrimination and Stigma. Almost half of the sample (43%) said they had been discriminated against or stigmatized due to their psoriasis, while 57% said they had never been treated this way (fig. 2). Those who had been discriminated against were slightly younger, with an average age of 31.47 years, than those who had not, with an average age of 50.04 years.

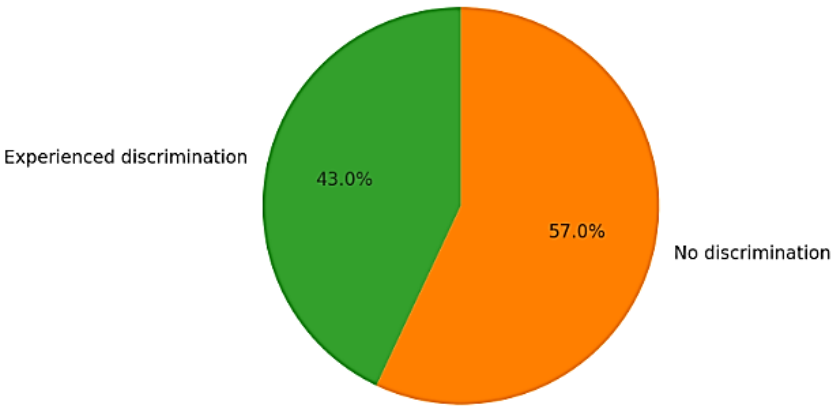

Fig. 2. Experience of discrimination or stigma due to psoriasis

Sleep Disturbances. Only 6.5% reported having insomnia or difficulty sleeping, while the majority (74%) did not have a sleeping problem (fig. 3).

Approximately 19% could not answer or were unsure of this question. No significant association was found between the experiences of discrimination and insomnia.

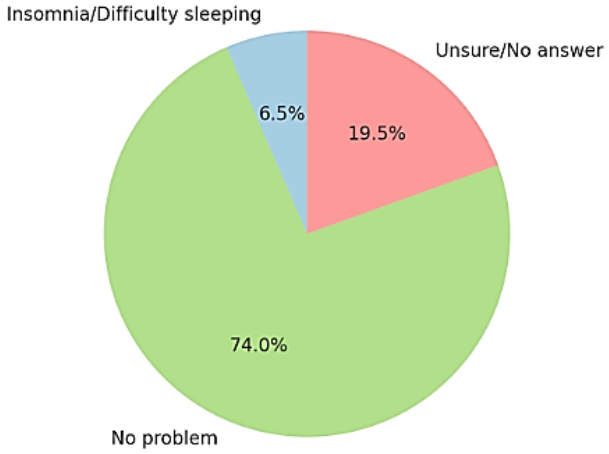

Fig. 3. Reported sleep disturbances among respondents

Expectations about Disease Course. The participants gave diverse responses when questioned about what they hoped for the psoriasis of their future (fig. 4). 42 out of 155 responders stated that they had no hope for the future of their disease. Though 29 participants wished to become totally well, 32 participants wished that they would improve. Five of the small sample predicted that their illness would worsen, and five predicted that any treatment that they received would be only temporarily effective. 29 subjects had not given a clear answer or were not sure how to respond, and 12 subjects had responded differently or more elaborately before.

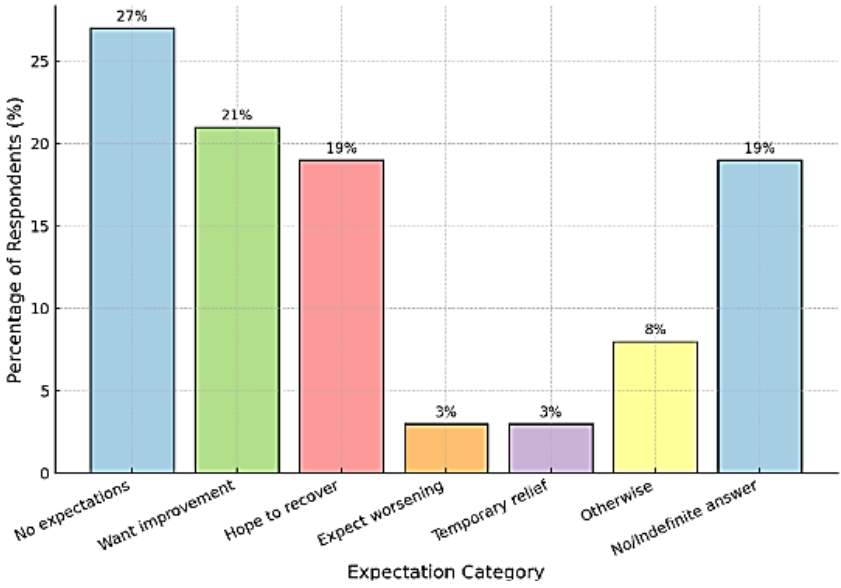

Fig. 4. Expectations about the future course of psoriasis

Impact on Family, Work, and Relationships.

When asked to describe how psoriasis had affected different parts of their lives, participants most often reported negative effects on a variety of important areas (fig. 5). Eighty-one reported that their families were affected negatively, and 76 reported that their performance at work was affected negatively as a result. Similarly, 84 reported that their dating relationships were affected negatively by their psoriasis. A little over 23 of the responses in these categories were either absent or too general to be categorized properly.

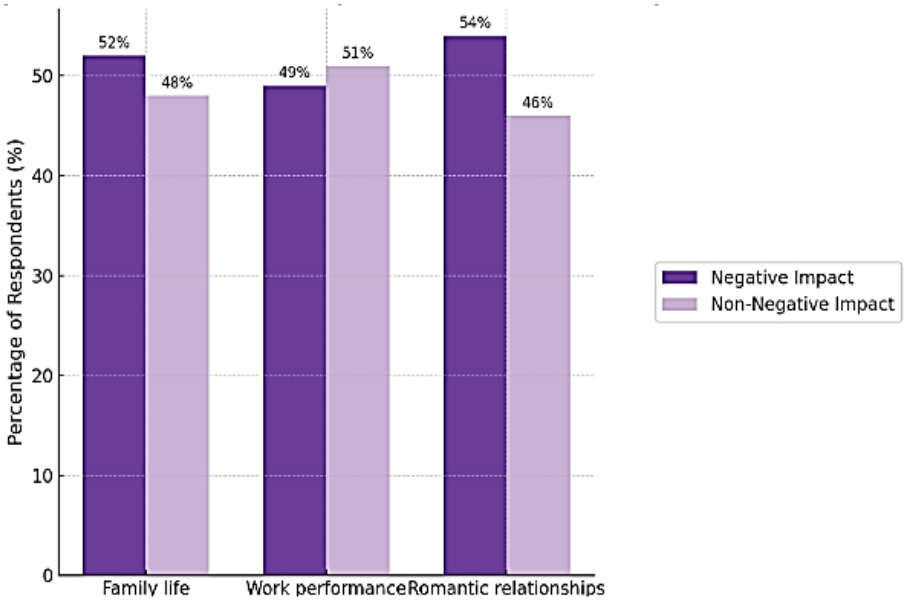

Fig. 5. Impact of psoriasis on family, work performance and romantic relationships

Psychosocial Correlations. There was a statistically significant and moderate relationship between discrimination reports and adverse effects on family, employment, and interpersonal relationships, suggesting that individuals reporting discrimination were more likely to report strain in these domains. Pearson's chi-square tests yielded χ^2 (9) = 32.26, $p < 0.001$, with Cramer's V = 0.388, indicating a moderate effect size. Discrimination was not significantly related to insomnia, though.

DISCUSSION

The study unveils the complex overlap of psoriasis and mental health, where psychosocial issues, led by discrimination, are the root cause of impaired quality of life. The study also has a few limitations. Self-report data limitation is prone to in-built subjectivity and recall bias. Female over-sampling (79%) and relatively low sample size might limit generalizability.

Nevertheless, the results offer significant patient-centered evidence to empha-

size imperatives of the integration of psychosocial issues into models of psoriasis clinical management.

Nearly half of the participants reported being stigmatized or discriminated against, consistent with earlier research placing psoriasis at the center of the most stigmatized dermatological disease (5). In 2021, Zhang *et al*. (12) mentioned that the lack of public understanding of these dermatological diseases would lead to people being stigmatized and treated with disgust and hostility. Also, stigma may lead to social rejection and internalization of negative self-beliefs, increasing emotional vulnerability and psychiatric comorbidity (3). Back in 2020, a similar survey was conducted by Wan *et al*. (13), in which they reported that 106 patients were stigmatized based on their psoriatic lesions. Two-thirds of the patients who completed this survey anticipated being stereotyped as contagious or unattractive, whereas about one-third of them thought that their lesions would elicit disgust from other people upon seeing them.

In contrast to studies with high levels of sleep disturbance among psoriasis patients, as often explained by pruritus, depression, and systemic inflammation (14, 15), the current sample had comparatively low levels of sleep complaint (6.5%), not correlated with a seeming association with insomnia and discrimination. This result may be explained by underreporting, the effect of non-psoriasis-related sleep disorder, or sample-specific characteristics. Lack of correlation indicates that stigma acts directly on psychosocial adjustment by means of relational stress and not by means of biological sleep disturbance. In a 2024 study guided by Guo *et al*. (16), fifteen studies including 1274 patients with psoriasis and 775 controls were analyzed, and they concluded that psoriasis is associated with sleep disturbances, especially among young patients. They also mentioned that patients with psoriasis are more likely to experience insomnia.

Contrary to expected responses, the disease course differentiated subgroups with no expectations from those with expectations of complete remission. These subgroups also showed higher perceived discrimination, although not significantly. Such trends may signal higher psychological vulnerability, whereby reduced hopefulness or excessive optimism increases the distress of social rejection. This aligns with earlier evidence that coping styles, resilience, and perceptions of illness significantly influence the psychological burden of psoriasis (17). After treatment, 72% of patients expected 90%-100% clearance, whereas only 28% expected <90% clearance of psoriasis in a study conducted by Clemmesen *et al.* in 2023 (18). So, it would be possible to suggest that some patients still have hope for clearance despite the odds.

Particularly, discrimination experience was most closely associated with adverse impact on family relationships, work functioning, and interpersonal relationships, indicating that the psychosocial morbidity of psoriasis extends far beyond individual self-esteem to influence central relational and functional areas of daily living. This extends beyond self-esteem to relational and functional domains, supporting Grossschaedl *et al.* (19) study from 2024 on high emotional burden for partners and relatives

The multivariable analysis identified

patterns in discrimination predictors, but none were statistically significant. Males experienced discrimination less frequently than females, and greater age was associated with a lower likelihood, patterns that could reflect gendered social dynamics or cumulative coping resilience over time. There was no prognostic role for insomnia. Notably, individuals who had no expectations about their illness or hopes for a full recovery were more likely to experience discrimination than those who anticipated improvement. This suggests that despondency or false optimism may increase feelings of vulnerability and social rejection.

CONCLUSIONS

Psoriasis has to be visualized as a multidimensional disease well beyond the scope of dermatopathology. Stigma and discrimination are placed in the focus of this article as parts of the forces that influence the psychosocial existence of patients and significantly lower quality of life in family, occupational, and relational areas of life. Systemic inflammation biologically links psoriasis with psychiatric disease, and social stressors raise disease burden and create a vicious circle of distress.

Effective management necessitates a careful, multidisciplinary strategy. Apart from biologic and systemic anti-inflammatory treatment, routine mental health screening, measurement of stigma experience, and availability for psychological and social support treatment are required. Cognitive-behavioral therapy, psychoeducation, and peer support interventions have the ability to empower patients to reconceptualize illness representations and become resilient. Integrative psychodermatology thus promises improved outcomes through management not just of overt cutaneous lesions but also of silent wounds of social discrimination.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

EXTRAINTESTINAL MANIFESTATIONS IN INFLAMMATORY BOWEL DISEASE - RESULTS FROM NORTH-EASTERN ROMANIA (Abstract): The presence of extraintestinal manifestations (EIM) in inflammatory bowel disease (IBD) is a common and well-known finding. **Material and methods:** Using the national database IBD Prospect, we conducted a prospective case-control study that included 325 patients diagnosed with Crohn's disease (CD) or ulcerative colitis (UC). Between these cases, 81 (24.92%) were classified in the group CD, 242 (74.46%) having UC and 2 cases (0.62%) were classified as having undifferentiated colitis. Among them, 30 patients (9,23%) had EIM including 24 cases of articular manifestations. Regarding joint events, we found 5 cases of arthritis, 10 cases having axial manifestations like sacroiliitis or ankylosing spondylitis and 9 cases of multiple EIM including articular damage. **Results:** In both study arms, articular manifestations occupy the first place into EIM (14/17 CD *vs.* 10/13 UC, 82.35% *vs.* 76.92%, p=0.927). Into the CD group, joint manifestations first correlated with the ileo-colonic form of CD (8/14; 57,14%) followed by the colonic involvement (4/14; 28,57%). Into the UC arm, joint damage was associated with an extended colonic involvement (4/10; 40%) followed by proctitis and left side colitis. Both groups of patients with articular manifestations were associated with a moderate form of IBD activity - 10/14 CD *vs.* 5/10 UC (71.43% *vs.* 50%, p = 0.199). **Conclusions:** Most patients included in this study and having EIM belong to CD phenotype. Articular manifestations occurred at a higher frequency in patients with CD as compared to those diagnosed with UC. The most common articular manifestation is the axial involvement, followed by peripheral arthritis. **Keywords:** INFLAMMATORY BOWEL DISEASE, CROHN'S DISEASE, ULCERATIVE COLITIS, ARTICULAR MANIFESTATIONS, EXTRAINTESTINAL MANIFESTATIONS.

Inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC), are chronic inflammatory diseases different from both the pathogenic mechanisms, as well as from clinical manifestations. In addition to inflammatory intestinal damage, CD and UC may have lots of extraintestinal manifestations (EIM). The most common EIM are at the level of musculoskeletal system - axial and peripheral arthritis, followed by skin involvement - erythema nodosum, pyoderma gangrenosum or eye damage - uveitis, iridocyclitis.

EIM can be divided into three catego-

ries: extraintestinal immune- related manifestations of IBD, autoimmune disorders associated to IBD and extraintestinal complications. Extraintestinal immune- mediated manifestations have the same pathogenic mechanism and correlate with the activity of intestinal inflammation. Autoimmune diseases associated with IBD develop independently of IBD activity and are characterized by a high genetic susceptibility. Extraintestinal complications may occur due to: intestinal inflammatory activity, use of medication, anatomical and metabolic changes that accompany IBD, malabsorption etc. (1, 2).

MATERIAL AND METHODS

We performed a prospective case-control study using the national database IBD PROSPECT (Inflammatory Bowel Disease Prospect). All patients signed an informed consent form before being included in the database. In University Center Iasi were included 325 patients with IBD. Among these, 140 (43.08%) were female and 185 (56.92%) male. Most patients were coming from urban areas - 227 cases (69.85%), while in rural areas were recorded only 98 cases (30.15%). The average age was 43 years with a minimum of 17 years and a maximum of 76 years. Among the patients included, 81 (24.92%) were classified in the group of CDs 242 (74.46%) in the UC's group and 2 cases (0.62%) were categorized as undifferentiated colitis. The detailed patient history also included the smoking status. 40 cases (12.30%) of smokers, 122 cases (37.54%) of ex-smokers and 163 cases (50.16%) of never-smoking were recorded.

All patients were examined clinically and paraclinically. The history followed significant personal or family history, the clinical symptoms like: the number of stools / 24 hours, the presence of rectal tenesmus, lower gastrointestinal bleeding, weight loss within 3 months, abdominal pain and asthenia.

Evaluation of the disease phenotype was performed using colonoscopy with biopsy and histopathological examination. CD has been divided, according to the localization of the inflammation, in L1 - ileal, L2 - colonic, L3 - ileo-colonic and depending on the type of disease in B1 - inflammatory, B2 - stenosing and B3 - penetrating disease. Depending on the location of the inflammatory process, UC was divided into E1 - proctitis, E2 - left colitis and E3 - extensive colitis. In both groups of patients, the assessment of severity of the disease flare was quantified by remission, mild, moderate or severe.

The study also analyzed the treatment of these patients. There have been considered the following classes of drugs: 5 ASA (5-aminosalicylic acid), corticosteroids, budesonide, the use of antibiotics, probiotics and immunosuppressive agents such as azathioprine, methotrexate or biological therapy with anti-TNF-α agents such as infliximab or adalimumab.

Regarding the complications related to the disease, they were divided into two categories: intestinal and extra-intestinal manifestations. The intestinal complications included: abscesses, intestinal and perianal fistulas, stenosis, the presence of toxic megacolon, intestinal perforation, lower intestinal bleeding and the development of a malignancy. Extraintestinal manifestations included joint signs like arthritis or sacroiliitis/ankylosing spondylitis (SI/AS), skin manifestations: erythema nodosum, pyoderma gangrenosum, eye manifestations: uveitis / episcleritis, gastrointestinal symptoms: peri cholangitis, primary sclerosing cholangitis or renal manifestations such as

oxalate nephrolithiasis, renal amyloidosis or multiple urinary infections.

RESULTS

In the study group, 30 cases (9.23%) with EIM were highlighted. Of these, we noticed 5 cases (16.66%) of arthritis, 10 cases (33.33%) of SI/AS, erythema nodosum 2 cases (6.66%), pyoderma gangrenosum 1 case (3.33%), 1 case of primary sclerosis cholangitis (3.33%), multiple urinary infections 2 cases (6.66%) and associations between two or more EIM - 9 cases (30%). Because all the cases with multiple EIM also have articular involvement, they were considered as articular manifestations, being in total 24 cases (80%) (tab. I).

In the group of patients who had articular manifestations (n = 24; 80%), 14 cases (58.33%) of axial manifestations (sacroiliitis/ankylosing spondylitis), 9 cases of arthritis (37.5%) and one case (4.16%) of association between peripheral and axial involvement were recorded (fig. 1).

TABLE I.

Extraintestinal manifestations in study group

Extraintestinal manifestation	n (%)
Articular manifestations (n, %)	24 (80%)
Arthritis	5 (16,66%)
SI/AS	10 (33,33%)
Association of EIM	9 (30%)
SI/AS + pyoderma gangrenosum	2 (6,66%)
SI/AS + uveitis/episcleritis	1 (3,33%)
SI/AS + uveitis/episcleritis + oxalate urolithiasis + multiple urinary infections	1 (3,33%)
Arthritis + multiple urinary infections	1 (3,33%)
Arthritis + erythema nodosum	1 (3,33%)
Arthritis + uveitis/episcleritis	2 (6,66%)
Arthritis + SI/AS	1 (3,33%)
Erythema nodosum (n, %)	2 (6,66%)
Pyoderma gangrenosum (n, %)	1 (3,33%)
Primary sclerosing cholangitis (n, %)	1 (3,33%)
Multiple urinary infections (n, %)	2 (6,66%)

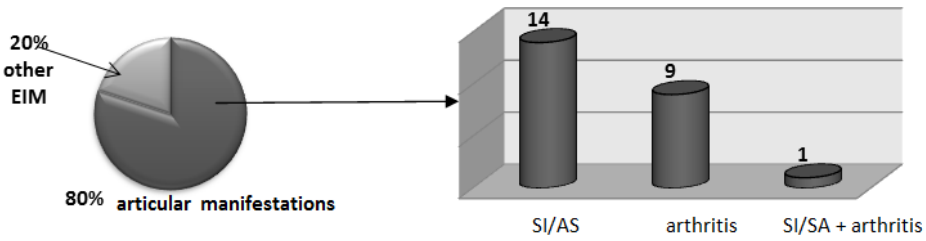

Fig.1. Articular manifestations in patients with IBD

CD and EIM

There were 17 patients diagnosed with CD who also had EIM as follows: 14 cases (82.35%) with articular manifestations, one case (5.88%) having erythema nodosum, 1 case (5.88%) with pyoderma gangrenosum,

1 case (5.88%) with multiple urinary infections. Most patients with CD and EIM were female - 11cases (64.70%) than male - 6 cases (35.30%). 16 patients (94.12%) were from urban areas, only one patient (5.88%) being from rural areas. The analysis of smoking status revealed the following data: 8 cases (47.06%) of active smokers, 3 cases of ex-smokers (17.65%) and non-smoking 6 cases (35.29%).

For patients with CD and EIM, the most frequent localization of the inflammatory process was L3 (ileo-colonic disease) - 9 cases (52.94%), followed by L2 (colonic disease) - 5 cases (29.41%), L1 (ileal disease) - 2 cases (11.76 %) and L4 (upper digestive tract disease) - 1 case (5.88%). Referring to the form of the disease, 13 patients (76.47%) had B1 (inflammatory form) and 4 patients (23.53%) had B2 (stricturing form). Most of cases - 11 (64.7%) - had a moderate intestinal inflammation, while 6 cases (35.30%) had remission or a mild form of BC (fig.2).

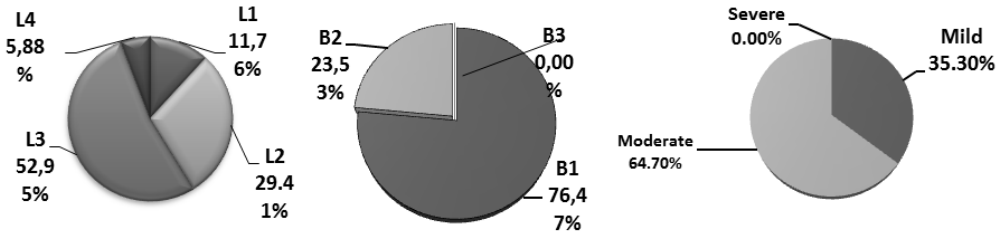

Fig. 2. Association between different forms of CD and EIM

The group of CD patients presented 14 cases (82.35%) of articular manifestations, which are the most common EIM. There were 3 cases (17.65%) of arthritis, 6 cases (35.30%) of SI/AS and 5 cases (29.41%) of association between different EIM including joint symptoms.

Articular manifestations occurred in a higher percentage in patients with L3 localization of CD - 8 cases (57.14%), followed by L2 - 4 cases (28.57%) and L1 - 2 cases (14.28%). The largest number of cases with an inflammatory phenotype (B1) - 11 (78.57%), followed by the stenosing form (B2) - 3 cases (21.43%), was recorded in subjects with associated articular manifestations. Also, moderate inflammation of the gut was associated with joint symptoms - 10 cases (71.43%), followed by the mild form - 4 cases (28.57%) (fig.3).

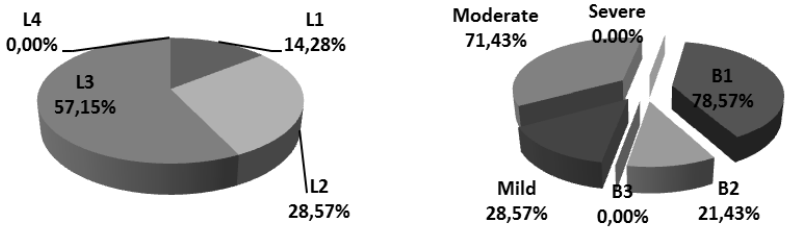

Fig. 3. Association between different forms of CD and articular manifestations

It should also be noted that patients with CD and EIM can develop intestinal complications. There were seven cases (41.17%) of such complications: 4 cases (57.14%) of stenoseses, 1 case (14.28%) of lower digestive hemorrhage, 1 case (14.28%) of fistulas + lower digestive hemorrhage, 1 case (14.28%) of abscesses + fistula. Of the 7 cases of intestinal complications, 6 (85.71%) have developed in patients who also associate articular manifestations.

UC and EIM

The group of patients with IBD include 13 cases of UC and EIM: 10 patients (76.92%) with joint manifestations, 1 patient (7.69%) with primary sclerosing cholangitis, 1 patient (7.69%) with erythema nodosum and 1 case (7.69%) of multiple urinary infections. Of these 13 cases of UC, 8 (61.54%) were women and five (38.46%) men. Most patients came from urban areas - 9 (69.23%), 4 (30.77%) being from the countryside. Analyzing the smoking status, we found 8 patients (61.54%) non-smoking, 5 patients (38.46%) ex-smokers, none active smoker.

The location of the intestinal inflammation in UC correlated differently with EIM. Therefore, left colitis (E2) was found in 6 cases (46.15%) of patients who associate EIM, extended colitis (E3) in 4 cases (30.77%) and proctitis (E1) in 3 cases (23,07%). Regarding the severity of the intestinal inflammation, 6 patients (46.15%) with EIM showed a mild form of the disease, 5 patients (38.46%) a moderate form, only 2 patients (15.38%) having a severe inflammation of the bowel (fig. 4).

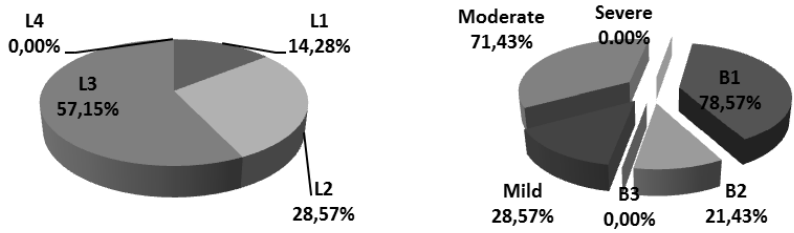

Fig. 4. Association between different forms of UC and EIM

Articular manifestations associated with UC were 10 (76.92%) distributed as follows: 2 cases (20%) of UC and arthritis, 4 cases (40%) of UC and SI/AS, 4 cases (40%) multiple EIM and UC.

According to the location of the inflammation of the bowel, articular manifestations associated with UC patients correlate as follows: 3 cases (30%) with form E1, 3 cases (30%) with form E2 and 4 cases (40%) with E3. The severity of the gut inflammation was divided into: 3 cases (30%) of mild symptoms associated with joint symptoms, 5 cases (50%) of moderate inflammation and 2 cases (20%) of severe bowel symptoms associated with axial or peripheral joint manifestations (fig. 5).

It must be pointed out that 2 patients (15.38%) with UC and EIM also associated intestinal complications such as lower digestive hemorrhage. Both patients had peripheral joint symptoms - arthritis.

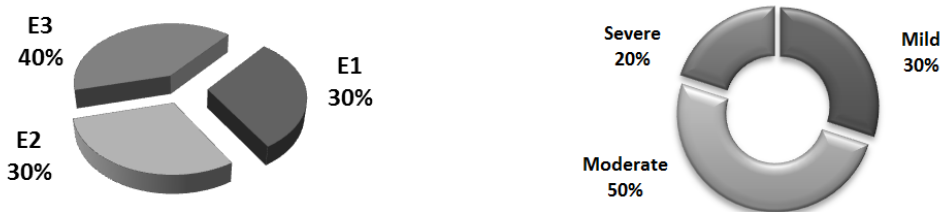

Fig. 5. Association between different forms of UC and articular manifestations

DISCUSSION

The aim of this study was to highlight the presence of EIM in patients with IBD. The overall prevalence of EIM found was 9,23% quite like that reported in the literature ranging from 6 and 47% (3-6). Both in the CD and UC group predominate female cases - 11/17 *vs.* 8/13 (64.70% *vs.* 61.54%, p = 0.838). Most patients come from urban areas - 16/17 CD *vs.* 9/13 UC (94.12% *vs.* 69.23%, p = 0.187). In the group of CD patients, 8/17 cases are active smokers, while in the case with UC patients 8/13 cases are non-smokers (p = 0.015) (statistically significant).

EIM occurred with a higher incidence among patients with CD and among females, this result being supported by other studies (7). In both study arms, articular manifestations have been shown to be the most frequent EIMs (14/17 CD *vs.* 10/13 UC; 82,35% *vs.* 76,92%, p=0,927). Numerous clinical trials have demonstrated that axial and peripheral articular manifestations occur frequently in patients with IBD, being classified as the most common EIMs (8-11).

In the group of patients with CD there is no difference between joint manifestations and other EIMs regarding the association with the location and the phenotype of the disease. Most cases of CD and EIM, including articular manifestations, correlated with form L3 (ileo-colonic) - 9/17 (52.94%), followed by form L2 (colonic) - 5/17 (29.41%). Regarding the phenotype, 11/17 (64,70%) had a moderate form of intestinal inflammation.

As opposed to patients with CD, in the group of cases with UC there is difference between joint manifestations and other EIMs regarding the association with the location and the phenotype of the disease. Most cases of UC and EIM correlated with left-colitis (E2) - 6/13 (46.14%), followed by pancolitis (E3) - 4/13 (30.77%). Regarding articular manifestations, they first correlated with pancolitis, then with left-colitis (4/10 *vs.* 3/10).

In both groups of patients with IBD and EIM, intestinal complications occurred with a higher rate in CD patients compared to those with UC - 7/17 *vs.* 2/13 (41.17% *vs.* 15.38%, p = 0.260). We raised the following hypothesis: a more severe disease characterized by the presence of intestinal complications can be considered as a risk factor for the emergence of EIM, including articular manifestations.

CONCLUSIONS

The results of our study confirmed that UC is more frequently found both in Northeastern Romania and in city of Iasi. Most of the patients enrolled in the study and who presented EIM belong to CD phe-

notype. Joint manifestations have been shown to be the most common EIM in both CD and UC patients. The most common articular manifestations are the axial forms (SI/AS), followed by peripheral arthritis. Joint manifestations occurred with a higher frequency among CD patients compared to those diagnosed with UC.

SHORT-TERM PREDICTIVE FACTORS FOR THE OUTCOME OF PRETERM INFANTS DEPENDING ON THE METHOD OF RESPIRATORY SUPPORT (Abstract): Respiratory support issues regarding preterm newborns show increasingly theoretical and clinical interest. **Aim:** To monitor the outcome of preterm infants with respiratory distress receiving different methods of respiratory support. **Materials and methods:** We performed a 5-year observational study (2013-2016) of 750 preterm infants with respiratory distress. The cases included in the study were divided into three groups as follows: group 1 - 476 premature newborns from IMSP IMsC (The Institute for Mother and Child Health) Chisinau (level III maternity hospital); group 2 - 240 premature infants transferred by the AVIASAN aerial service from level I and II to level III maternity hospitals, and group 3 - 34 premature babies from IMSP IMsC Chisinau which received surfactant administered by the LISA (Less Invasive Surfactant Administration) method. Data were analyzed using *SPSS 21.0* software (IBM Statistical Package for the Social Sciences, Chicago, Illinois). **Results:** 42.67% of the cases did not require initial respiratory support and in 36.8% of cases, CPAP (Continuous Positive Airway Pressure) was used. Of the cases which were at first on CPAP, 6.27% were transferred on conventional mechanical ventilation (CMV) and 4.8% on high frequency ventilation (HFV). Of the newborns who initially received CMV, 5.33% were later transferred on CPAP and 4.13% required HFV. Our results showed that mechanical ventilation had been applied particularly in low gestational age newborns - the mean gestational age was significantly lower in these infants ($p < 0.01$). Both in newborns from level III perinatal center and those from level I and II maternity hospitals, gestational age was significantly lower in those who required CMV or HFV. **Conclusions:** Due to the implementation of contemporary methods of respiratory support for preterm infants their survival rate has greatly improved. However, the possibility for oxygen therapy remains limited in low-resource settings. Thus, in the Republic of Moldova, high quality respiratory support remains a valid option only for the level III perinatal center - IMSP IMsC. **Keywords:** PREMATURE NEWBORN, MECHANICAL VENTILATION, CPAP, T-PIECE RESUSCITATOR, RESPIRATORY DISTRESS SYNDROME.

The most frequent acute respiratory disease for very premature infants is Respiratory Distress Syndrome (RDS). Treatment includes respiratory support and surfactant replacement therapy. The recent development of methods for respiratory management of the preterm infant in the delivery room includes limiting the use of excess oxygen during resuscitation and limitation of inspiratory pressure through using a T-piece resuscitator, which can be also used for early non-invasive ventilation and surfactant administration (1).

Some authors have highlighted the need to improve therapeutic strategies in the delivery room for fragile newborns. Jobe and other authors (1-3) mentioned that only few very low birth weight infants need resuscitation, while most of them only require transitional assistance to adapt to extrauterine life. While early CPAP safety and effectiveness are well established (2, 4, 5), the most effective approach to the preterm newborn with respiratory distress is a combination of early administration of surfactant during spontaneous breathing with CPAP support and with limited exposure to positive pressure ventilation.

Although many premature infants can be successfully treated with non-invasive ventilation, intubation should not be overlooked as a variant of respiratory support with long-term benefits. Children with severe RDS can continue to deteriorate despite non-invasive ventilation and there is a potential risk of administering high positive-end-expiratory pressures (PEEP) with very high levels of inspired oxygen. Signs of worsening of respiratory distress in a newborn, such as PEEPs > 7 cm H_2O, oxygen concentrations > 40% or pH < 7.25 are accepted as triggers for increasing respiratory support. Some researchers confirm that by using these criteria, the duration of mechanical respiratory support is reduced (6-9).

The aim of our research is to monitor the outcome of preterm infants receiving different methods of respiratory support and surfactant administration.

MATERIAL AND METHODS

We performed an observational study of 750 preterm newborns admitted between 2013 and 2016 to the Neonatal Intensive Care Unit (NICU) of the Institute for Mother and Child Health (IMSP IMsC) in Chisinau, Republic of Moldova. The cases included in the study were divided into three groups as follows: group 1 - 476 premature newborns from IMSP IMsC Chisinau (level III maternity hospital); group 2 - 240 premature infants transferred by the specialized aerial AVIASAN service, from level I and II to level III hospitals and group 3 - 34 premature infants from IMSP IMsC Chisinau which received surfactant by the LISA method. Infants in group 3 were selected throughout the year 2016, based on the clinical and radiological severity of the RDS and the presence of spontaneous breathing.

The inclusion criteria were respiratory distress, either due to surfactant deficit or congenital pneumonia, and gestational age less than 34 weeks. The exclusion criteria were: congenital malformations, genetic syndromes and hydrops fetalis (immune and non-immune).

To assess the outcome of the infants, we considered the following complications while infants were hospitalized in the NICU: pulmonary hemorrhage, intraventricular hemorrhage, air-leak syndromes, ventilator associated pneumonia, and chronic lung disease.

Data were analyzed using the *SPSS 21.0* software (IBM Statistical Package for the

Social Sciences, Chicago, Illinois). Continuous variables with normal distribution were expressed as mean ± standard deviation, and continuous variables with abnormal distribution were expressed as median (min-max). Categorial variables were expressed as absolute or relative frequencies. Continuous variables were verified by either the Levene test or Kruskal-Wallis test. The statistical significance level (p-value) was considered 0.05. The multivariate analysis used the multinomial logistic regression and the odds-ratio (OR) was calculated for each predictive parameter.

RESULTS

There are significant statistical group differences regarding gestational age (GA): 30.2 weeks in group 1, 30.8 weeks in group 2 and 29.1 weeks in group 3 (p=0.003).

There were 8.61% infants in group 1 and 6.25% infants in group 2 who received positive pressure ventilation in the delivery room. 37.92% neonates in group 2 and 27.94% in group 1 did not require respiratory assistance in the delivery room (Table I). Our results show a significant correlation between the method of initial respiratory support and the level of maternity hospital where the premature birth occurred (χ^2=139.2, p<<0.01, r=-0.642, 95%CI) (tab. I).

There is also a significant correlation between the resuscitation method and subsequent respiratory support (r=0.543, p<<0.01). Thus, the frequency of cases that required CPAP in the NICU was significantly higher (56.9%) in infants who received T-piece PEEP in the delivery room, compared to those which received initial bag and mask ventilation during resuscitation (tab. I). The latter were more likely to require mechanical ventilation, either from the start, or due to CPAP failure.

The overall need for respiratory support after delivery room management was 59.5% in group 1 and 47.1% for infants in group 2. In group 3, the need to switch from non-invasive respiratory support (CPAP) to conventional mechanical ventilation (CMV) was noted in 11.8% of cases (n=4), and from CPAP to rescue high-frequency ventilation (HFV) in 8.82% cases (n=3).

There was a significant statistical correlation between the method of respiratory support and the level of care provided by the maternity hospital in which the babies were born. This correlation can be explained by the significantly increased frequency of CPAP use in group 1 newborns (38.4%) compared with rates found in group 2 (27.5%). Also, the need for CMV was of 7.1% of cases in group 2 and only 4.8% in group 1. Both in groups 1 and 2, GA was significantly lower in neonates who required invasive respiratory support.

The assessment of need for respiratory support in our study showed that 52.9% of infants in group 2 and 38.2% infants in group 1 did not require respiratory support during their first day of life. This had significantly changed afterwards: the frequency of infants in group 2 requiring respiratory support was significantly higher compared to group 1 (χ^2=33.12, p<<0.01, r=0.404, 95%CI). Meanwhile, newborns in group 3 became rapidly respiratory independent.

Respiratory support using CPAP showed significant differences between the study groups: in group 3 it was only necessary during the first day of life. For newborns in group 2, the use of CPAP in the first day of life was 34.2% compared with 47.7% in group 1, and increased significantly later, after being transferred to a level III facility (χ^2=36.203, p<<0.01, r=0.321, 95%CI).

TABLE I

Estimated parameters for the methods of respiratory support in preterm infants

		Totals	Premature infants			Univariate analysis
			Group 1 Level III (n=476)	Group 2 Level I, II (n=240)	Group 3 Level III + LISA (n=34)	
Respiratory support in the delivery room	Without	224 (29.87%)	133 (27.94%)	91 (37.92%)	0 (0%)	$\chi^2_{Pearson}$=139.29, p<<0.001* $r_{Spearman}$=-0.642

		Resuscitation method	No resuscitation	T-piece PEEP	Bag-and-mask PPV	
Subsequent respiratory support	Without		249 (66.76%)	26 (12.44%)	45 (26.79%)	$\chi^2_{Pearson}$=209.98, p<<0.001* $r_{Spearman}$=0.548
	CPAP		95 (25.47%)	119 (56.94%)	62 (36.90%)	
	CMV-HFV-CMV-CPAP		4 (1.07%)	13 (6.22%)	14 (8.33%)	
	CMV-CPAP		6 (1.61%)	19 (9.09%)	15 (8.93%)	
	CPAP-CMV-CPAP		11 (2.95%)	14 (6.70%)	22 (13.10%)	
	CPAP-HFV-CMV-CPAP		8 (2.14%)	18 (8.61%)	10 (5.95%)	

Continuous variables: mean ± standard deviation; categorical variables: number (%) *p-value <0.05 was statistically significant, LISA - Low Invasive Surfactant Administration, CPAP - Continuous positive airway pressure, CMV - Conventional mechanical ventilation, HFV - High-frequency ventilation, PPV - Positive pressure ventilation, PEEP - Positive end-expiratory pressure

Variations between study groups 1 and 2 were found regarding CMV after 7 days of life, with a significantly higher frequency of newborns requiring CMV in group 2 compared to group 1 (χ^2=25.83, p=0.0002, r=0.573, 95%CI).

Respiratory support provided by HFV was frequently found in group 1 neonates within 7 days of life (χ^2=450.81, p<<0.001, r=0.202, 95%CI), while in group 2 it was used more often after the first week.

Our study showed that mechanical ventilation has been particularly used in cases with lower gestational ages, in all study groups (H_{KW}=159.02, p<<0.01, 95%CI).

The multivariate analysis showed that the method of respiratory support throughout the stay in the NICU was significantly influenced by the method of resuscitation (OR=3.57, p=0.0007) and the level of maternity care of the hospital in which the preterm infants are born (OR=2.5077, p=0.0021). GA and birth weight were also important factors that influence the method of subsequent respiratory support, but to a lesser extent (OR=1.67, p=0.0045; OR =2.13, p=0.0028) (tab. II).

Regarding complications in the NICU, the multivariate analysis showed that the method of respiratory support (OR=4.25, p=0.007) and the level of maternity care (OR=3.19, p=0.002) are major predictive factors. Also, the method of resuscitation (OR=2.91, p=0.0014), GA (OR=1.91, p=0.015) and birth weight (OR=1.83, p=0.0012) are also important for the incidence of complications during NICU stay (tab. III).

TABLE II

Multivariate regression analysis - predictive factors for the method of respiratory support

Multinomial Logistics Regression (predictive factors)		Beta	SE	Wald	Sig. p-level	Exp(β) OR	95% CI for Exp(B)

CI - confidence interval, exp(β)=OR-(odd ratio), SE-standard error								

DISCUSSION

Respiratory distress is one of the most common conditions encountered in preterm infants. Due to significant progress in medical technology, most of them will achieve full health with the assistance of varying levels of breathing support currently found in the NICU.

Currently, the most common form of respiratory support used in the delivery room is early CPAP with the aid of the T-piece resuscitator. This is a minimally invasive method that can provide a suitable PEEP for lung recruitment in a premature infant, thus maintaining an appropriate residual lung capacity and has been proven to be superior to positive pressure ventilation (10). However, this method is limited to infants with mild-to-moderate respiratory distress and spontaneous breathing and is not usually suitable for severe respiratory symptoms.

The early use of CPAP is associated with a significant reduction in the need for intubation (11). Various studies have pointed to the superiority of CPAP, with PEEPs of 5-7 cm H_2O to bag-and-mask ventilation in the delivery room (12). CPAP is also associated with lower rates of need for exogenous surfactant, respiratory failure and mortality (13). Surfactant administration is a costly intervention with limited availability. When CPAP is available in the delivery room, surfactant is no longer indicated for the prevention of RDS, only as early selective treatment once the symptoms of RDS occur (14). Our study also showed that the use of early CPAP in infants born in our level III hospital (groups 1 and 3) is associated with lower rates of later invasive mechanical ventilation. Unfortunately, not all level I and II maternity hospitals in the Republic of Moldova and Romania are equipped with T-piece resuscitators capable of providing CPAP in the delivery room. Also, the staff is reluctant to use such modern devices, despite their proven benefits.

Even when administered by an experienced physician, bag-and-mask ventilation

used during neonatal resuscitation can have deleterious effects, both due to the inadequacy and inconsistency of delivered pressures and volumes and the high concentration of oxygen that is used when gas blenders are unavailable (15).

However, the use of CPAP in the delivery room may fail in some infants, especially those of extremely low birth weight, as many of these require further endotracheal intubation followed by mechanical ventilation. This can probably be explained by the unnecessarily delayed surfactant therapy in these infants. In our study, about 23% of neonates required CMV after CPAP failure and some of them even required rescue HFV. Also, infants who fail early CPAP exhibit more complications, such as pneumothorax, chronic lung disease and intraventricular hemorrhage, and have a higher mortality compared to those in which early CPAP is used successfully (16).

Neonatal Intensive Care Units are increasingly adopting a gentle approach to ventilator support in preterm infants as standard care. Minimally invasive surfactant administration is part of this approach, as it does not require sedation, minimizes airway injury and avoids placing positive pressure ventilation on an immature lung. Moreover, it has been proven to be as effective as the moderately invasive technique of surfactant therapy (17). In our study, group 3 infants, who received surfactant through the LISA method, had a lower mortality rate, despite their lower GA.

The outcome of preterm infants requiring respiratory support depends on a multitude of factors, such as GA, the use of surfactant, the method, the duration or the concentration of oxygen used during respiratory support (8). In our study, the most important factor, for both the method of subsequent respiratory support and mortality is the level of maternity care of the hospital in which the infants are born. Our data are similar in this aspect to the findings of Marlow et al. (18). The level of care also impacts the methods used during resuscitation and the available technologies required for the long-term management of preterm infants, especially ELBW neonates.

The availability of new methods and techniques of management for various neonatal conditions is a crucial factor for the improved survival and outcome of preterm infants. Less Invasive Surfactant Administration is a somewhat revolutionary treatment method in neonatology with emerging benefits, such as pain reduction, increased comfort and low risk of complications due to intubation and mechanical ventilation (19). Our study also showed a significantly lower rate of complications and mortality in infants treated with LISA, compared to the other two groups.

CONCLUSIONS

The treatment of RDS in the preterm infant remains a challenge for neonatologists. Our study showed that due to the limited availability of modern therapeutic methods, the morbidity and mortality of preterm infants born in low-resource settings (level I and II maternity hospitals) are higher. Early use of non-invasive respiratory support such as CPAP is highly beneficial in such cases and leads to fewer and less extensive admissions to the NICU, less oxygen use, less lung damage caused by mechanical ventilation, and fewer complications. Also, surfactant administration by non-invasive methods, even when performed in extremely preterm infants is strongly correlated with a lower rate of complications and mortality.

THE UTILITY OF SERIAL EVALUATION OF cTnI AND BNP IN EARLY DETECTION OF ANTHRACYCLINE-INDUCED CARDIOTOXICITY IN CHILDREN (Abstract): **Aim.** Early detection of chemotherapy cardiotoxicity in pediatric patients by using sensitive and specific methods. **Material and methods**: The study group included 34 patients with malignancies, aged between 3-18 years. We evaluate the patients through history, physical examination, electrocardiogram, 2D/ Doppler echocardiography, cardiac biomarkers - BNP (B-type natriuretic peptide) and cTnI (cardiac troponin I), at baseline and subsequently, in dynamic. **Results:** Cardiotoxicity was revealed in 24 patients (70.5%), with clinical manifestations in 2 cases (5.8%). Echocardiographic changes were found in 26 cases (76.4%) (16 cases-47% with systolic dysfunction, 26 cases-76.4% with diastolic dysfunction), electrocardiographically changes in 73.5% of cases. Elevated plasma BNP was found in 18 patients-52.9%, and cTnI levels were normal in all patients (cut-off 0.04ng/mL). Elevated levels of BNP have been correlated with the cumulative dose of anthracyclines and therapeutic protocol received. **Conclusions:** The study may give solutions for the reduction and prevention of cardiotoxicity, even when are used higher doses of anthracyclines with a higher rate of healing while improving the quality of life of survivors. **Keywords**: CARDIOTOXICITY, CYTOSTATICS, CHILD, DIAGNOSTIC, ANTHRACYCLINE.

Anthracyclines (ANT) are one of the most effective and commonly used antineoplastic agents in treatment of cancer in children. Their use has positively influenced the outcome, increasing substantially the survival rate. However, this benefit is encumbered by a high rate appearance of anthracycline-induced cardiotoxicity (1).

Over the years, many researchers have used various methods to assess the cardiotoxicity, to an early highlight and initiation of preventive measures. Cardiotoxicity detection by imaging methods (echocardiography, radio-nuclear angiography) has major limitations, emphasizing late left ventricular dysfunction and allowing objectifying the toxic effects only when is enough damage on the heart to cause functional disorders. Recent studies on cancer patients showed that elevated levels of B-

type natriuretic peptide (BNP) and troponin I(cTnI) may serve as a predictor of infraclinical phase of cardiotoxic effect of chemotherapy, allowing the stratification of cardiac risk in a very early phase, long before heart function decreasing and symptoms appearance, when many of preventive therapeutic strategies are effective (2, 3).

In this article, we expose the results of a prospective study which aimed to assess the sensitivity of cardiac biomarkers (BNP, troponin I) in the early detection of cardiotoxicity and to establish possible strategies in identifying patients at elevated risk of developing anthracyclines cardiomyopathy.

MATERIAL AND METHODS

The study group included 34 patients, 16 girls and 18 boys, aged between 3 and 18 years, admitted in a pediatric oncology-hematology clinic for one year period. The children have followed therapeutic protocols for various malignancies that included also anthracyclines.

The study was approved by the ethics committee of our hospital. Patients were included in the study only after informed consent was obtained in writing, from legally belongs of the children.

The median dose of anthracyclines (doxorubicin) administered during the study was 226 mg/m², with the minimum-maximum range of 50–920 mg/m². Additional to anthracycline treatment, patients received other cardiotoxic chemotherapy, which increased the risk of cardiotoxicity.

Cardiac assessment included clinical examination, cardiothoracic radiography (with cardio-thoracic index calculated), electrocardiogram (EKG), echocardiography (ECHO) 2D/Doppler and biochemical markers dosing (cTnI, BNP). No patient presented cardiac disease prior to the enrollment in this study. No cardioprotective treatment was administered during the study, except for two patients who developed heart failure, in which specific treatment required.

Echocardiographic evaluation was performed by a single pediatric cardiologist. Echocardiographic evaluation was performed before treatment and, subsequently, after each cycle of chemotherapy that included ATC, at 6 and 12 months after initiation of chemotherapy. The followed parameters were: ejection fraction (EF) and shortening fraction (SF) for systolic function, the peak early filling (E-wave) and late diastolic filling (A-wave) velocities, the E/A ratio, isovolumic relaxation time (IVRT), peak systolic (S) velocity, peak anterograde diastolic (D) velocity, the S/D ratio, isovolumic contraction time(ICT) for diastolic function, mixed parameters for systolic and diastolic function and myocardial performance index- Tei index. The average number of echocardiography for each patient was 6, with certain intervals: at baseline and then after each of the first 3 cycles of anthracycline, and additionally as needed.

The assessment of specific BNP and cTnI biomarkers was done at baseline (before initiating therapy) and in dynamic, depending on the time of administration of ATC - before and after administration of cytostatic infusion-, for a period of 12 months. The method used for detection was Microparticle Enzyme Immunoassay (MEIA). The device used was ® System AxSYM-Abbott Laboratories. We used the cut-off values suggested by the manufacturer: quantitative determination of cardiac troponin I - cTnI in serum - cut-off value troponin I < 0.04ng/mL, respectively quantitative determination of BNP in plasma - BNP cut-off value 100pg/mL. Values obtained from analysis of plasma BNP and

cTnI are controlled using the controllers both during calibration and proper analysis (double-blind).

Statistical analysis was performed with *SPSS*, version 15.0. Descriptive and inferential statistical analysis was done. Correlations between variables were calculated using the correlation coefficient test of Pearson's. Regression analysis was also effectuated. Statistical significance was set for a p-value <0.05.

RESULTS

Characteristics of the study group are shown in Table I. From the study group, 27 patients were still alive at the time of study completion; death of seven patients was determined by the evolution of the underlying disease and not by a possible secondary damage of heart function.

TABLE I.
Characteristics of the study group

Parameters		Number	Percent %
Sex	female	16	47.1%
	male	18	52.9%
Age	< 6 years	16	47.1%
	6-10 years	8	23.5%
	11-18 years	10	29.4%
Diagnostic	ALL	18	52.9%
	NHL	6	17.6%
	Sarcom	2	5.9%
	AAML	2	5.9%
	HL	5	14.7%
	others	1	2.9%
Echocardiographic changes	yes	26	76.5%
	no	8	23.5%
Decreased EF >10%	yes	18	52.9%
	no	16	47.1%
Decreased SF >10 %	yes	23	67.6%
	no	11	32.4%
EKG changes	yes	25	73.5%
	no	9	26.5%
BP changes	yes	6	17.6%
	no	28	82.4%
Cardiotoxicity	no	10	29.4%
	infraclinical	22	64.7%
	clinical	2	5.9%

The cardiotoxicity manifestations were grouped into two: 1) clinical type – with clinical signs and symptoms of heart failure (dyspnea, fatigue) and changes in paraclinical investigations (echocardiogram, EKG, cardiac biomarkers) and 2) subclinical - asymptomatic patients, but with significant changes highlighted in systolic or diastolic function. 22 cases (64.7%) were asymptomatic and 2 cases of heart failure occurred (5.9%). Other cardiological changes during evaluation were variations in BP values (6

cases), electrocardiographic changes (73.5% cases). EKG alterations were represented by minor changes in left ventricle repolarization, QT prolongation, supraventricular tachycardia (24 patients) and 1 case of AV block grade III.

Echocardiographic changes were seen in 76.5% of cases; most of them were transient, occurring immediately after taking cytostatic, later return to normal baseline. Decrease by> 10% of the EF or SF was found in 53%, respectively, 67.7%of cases, although the actual value of the FE and/or SF has not dropped below the lower limit of normal. In 1 case EF was <40% and 14 cases SF <28%. This is considered more representatives in appreciation of cardiotoxicity events. Changes in diastolic function were more common, 26 cases and Tei index increased was found in 14 cases (tab. II).

TABLE II.
Cardiac modification after ATC

Cardiac Assessment	Cardiac modification	Number	Percent %
Echocardiography	normal	8	23.5
	decreased EF by > 10%	18	52.9
	decreased SF by>10%	23	67.6
	modification of LV diastolic function	26	76.5
	modification of LV systolic function	16	47.1
EKG	normal	9	26.5
	modified	25	73.5
BNP levels	< 100 pg/mL	16	47.1
	100 - 200 pg/mL	6	17.6
	200 - 500 pg/mL	9	26.4
	> 500 pg/mL	3	8.8
BNP categories	A- normal	16	47.1
	B - transient increase further normalization	12	35.2
	C- increased	6	17.6
cTnI levels	< 0,04 ng/mL	34	100
	> 0,04 ng/mL	0	0
BP	normal	28	82.4
	high	6	17.6
Cardiotoxicity	no	10	29.4
	infraclinical	22	64.7
	clinical	2	5.9

BNP's elevated levels in plasma, above the cut-off of 100 pg/mL, were funded at 52.9% of cases. According to the BNP values changes during the study, they were divided into 3 groups: group A normal levels, group B - BNP levels were elevated, but later returned and were maintained in the normal range, and group C- BNP levels have remained elevated. The increased plasma levels of BNP were positively correlated with the administered dose of anthracyclines and type of chemotherapy followed protocol (fig.1, 2).

Serum cTnI levels did not exceed the cut-off value of 0.04 ng/mL in any patient in the study group, both baseline and in dynamics. Only 3 patients had cTnI value of 0.04 ng/mL, considered be the normal value.

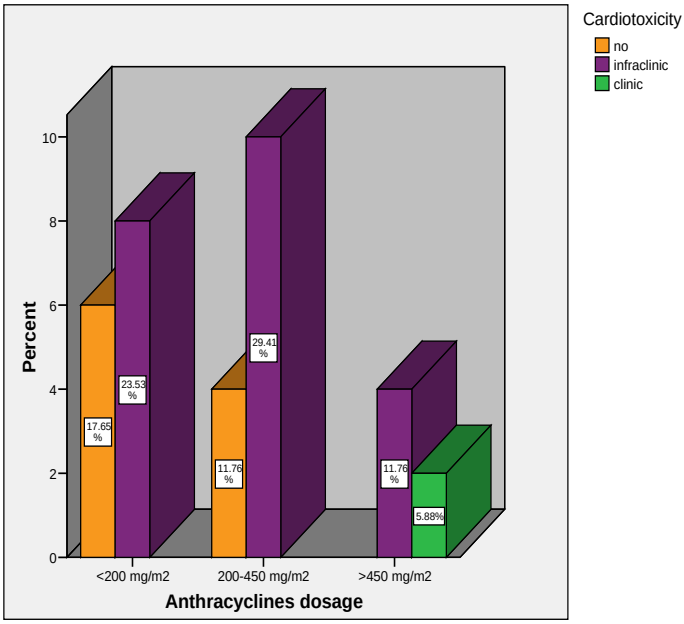

Fig.1. Correlations between the cumulative dose of anthracycline and emergence of cardiotoxicity

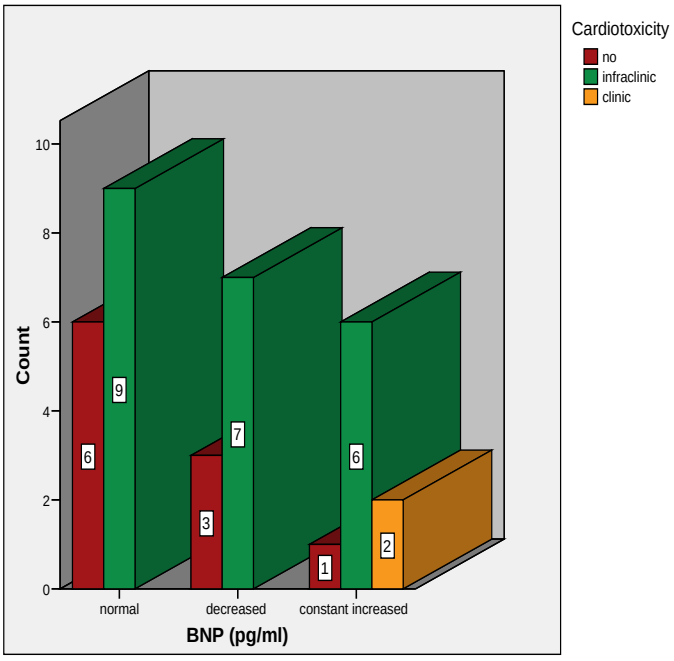

Fig. 2. Correlations between the BNP dynamics and emergence of cardiotoxicity

In the current study, cardiotoxicity was positively significant correlated decreased EF> 10% (r = - 0.457, p = 0.007), decreased SF >10%(r = -0.508, p = 0.002), pathological BP (r = - 0.341, p = 0.048), higher cumulative anthracycline dose (r = 0.505, p = 0.02) and higher serum BNP levels (r = 0.465, p = -0,006).

Scatterplot diagram of the relationship between the cumulative dose of anthracyclines and BNP value suggested a positive linear correlation. Accurately predicting the BNP levels depending on the cumulative anthracyclines dose is made by the relation:

Y = - 49 657 (1,099 x) in which x = the individual cumulative dose of anthracyclines and Y = the best predictive value for the individual BNP.

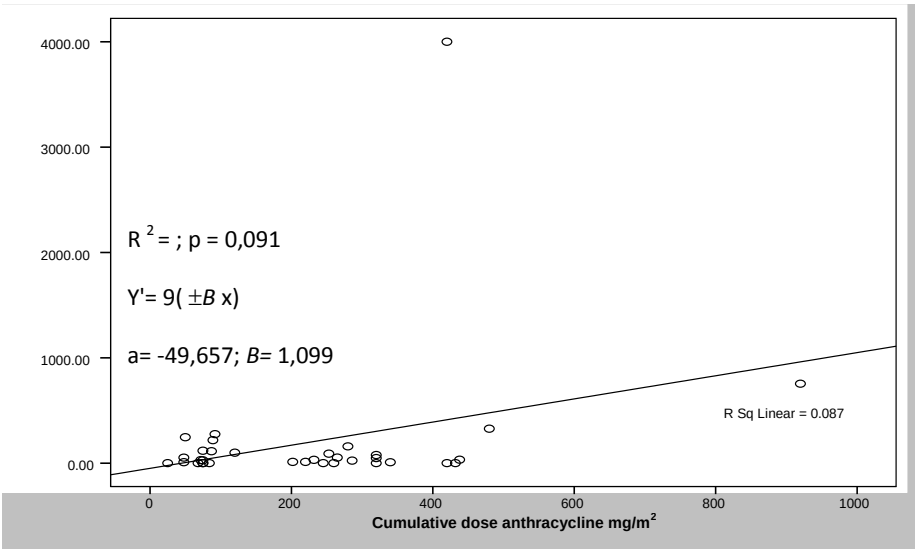

Fig. 3. Linear regression analysis between BNP levels and cumulative anthracycline dose

DISCUSSION

The study highlights the presence of anthracycline cardiotoxicity in pediatric oncologic patients with a considerable 70.6% incidence. The data obtained in this study correlate with the results referenced studies published in the literature (2, 3, 4). It stands high percentage of infraclinical cardiotoxicity (64.7%). Many of the clinical manifestations are nonspecific and may be misinterpreted. They are routinely assigned to the malignant disease, leaving laboratory investigations to early highlight the changes (2).

The first echocardiographic changes in our patients were those of diastolic function subsequent appeared and the systolic function. We did not found positive statistically significant correlation between electrocardiographic changes and the emergence of cardiotoxicity; this result is consistent with the results reported by other authors (5, 6, 7, 8).

As shown in other studies (5, 6, 7, 8), paraclinical method of choice is to evaluate serum levels of BNP and cTnI, that correlates with echocardiographic assessment. Evaluation of serum BNP and cTnI is a non-invasive, easily reproducible, with substantially reduced cost compared echo-

cardiogram or other imaging method.

The results obtained in the present study confirm the data reported in the literature, that there is a significant relationship between increasing plasma BNP levels and cardiac dysfunction both in symptomatic patients, asymptomatic and treated with anthracyclines.

Clinically asymptomatic patients, but which remained elevated BNP's during the entire period of the study, can be considered at elevated risk of developing anthracycline cardiomyopathy. In a relatively small number of cases were highlighted elevated BNP levels prior to anthracyclines treatment initiation which may suggest that there are other factors that influence myocardial wall stress (anemia, tachycardia), but these factors were not seen in the time in the group patients. The great marginal significance prognosis correlation between anthracyclines cumulative dose and higher levels of BNP ($r = 0.295$, $p = 0.091$), in terms of a strong relationship between elevated BNP and cardiotoxicity, as well as a strong relationship between higher anthracyclines cumulative dose and cardiotoxicity, suggests that other conditions which influence the BNP values deserve to be considered for further studies. In some patients, changes in biomarkers and echocardiography were transient. This emphasizes the need of monitoring initial and in dynamic status, to confirm whether patients with subclinical changes will develop cardiomyopathy over time and where is appropriate to start a cardioprotective treatment

The results on studying serum cTnI levels were according to the data obtained from other important studies in the literature (2, 3, 4), but larger studies are needed to establish whether this biomarker can be used to predict cardiotoxicity.

It is important to note that there is an individual variability in the relation between cumulative dose - cardiotoxic response, so efforts aimed to prevent cardiovascular morbidity due to anthracyclines should be channeled more on early detection of cardiotoxic effects than in chemotherapeutic protocols changes (9, 10).

CONCLUSIONS

Early detection of cardiotoxicity after anthracycline therapy and highlighting the patients at risk is a goal of many researchers in the field. Our results showed that there is a significant relationship between increasing plasma BNP levels and cardiac dysfunction both in symptomatic and asymptomatic patients treated with anthracyclines. BNP assessment at the initiation of treatment and subsequently in dynamics is useful in highlighting patients at increased risk of developing cardiotoxicity, and to establish therapeutic strategies to prevent installation of severe heart damage, improving the overall outcome of these patients. Studies are needed on large groups of patients, to have a proper perspective of the data obtained.

NEWS

PATHOLOGY OF ISCHEMIC OPTIC NEUROPATHY

Ischemic optic neuropathy (ION) refers to infarction of any portion of the optic nerve from the chiasm to optic nerve head. Clinically, it is divided into anterior and posterior forms by the presence or absence of swelling of the optic nerve head, respectively. Both forms are further classified into arteritic when secondary to vasculitis and nonarteritic when caused by other entities. Nearly all cases of arteritic ION are due to giant cell arteritis. The pathogenesis of nonarteritic anterior ION is unsettled, but the clinical diagnosis encompasses several distinct, albeit uncommon, sources of injury including thromboembolism, systemic hypotension, and atherosclerotic vascular occlusion. Systemic hypertension, diabetes mellitus, and sleep apnea have been associated with nonarteritic anterior ION, but in most cases no direct underlying cause for vascular insufficiency is found. Occasionally referred to as ‘‘common’’ or ‘‘idiopathic,’’ nonarteritic anterior ION tends to affect optic discs with a small-diameter scleral canal and optic cup, the socalled disc at risk. Based on conventional use of the term, ischemic optic neuropathy refers to the acute stages of ischemic injury before optic atrophy develops. Ischemic optic neuropathies are common clinical conditions, with the incidence of nonarteritic anterior ION between 2.3 and 10.3 per 100 000 population per year. Despite the overall prevalence of ION clinically, eyes with acute ION are rarely encountered in the pathology laboratory, and then usually in the context of autopsy as an incidental finding, or in specimens removed surgically for other primary reasons (Patel HR, Margo CE. Pathology of Ischemic Optic Neuropathy. *Arch Pathol Lab Med*. 2017; 141:162–166).

THE ROLE OF KINESIOTHERAPY IN THE MANAGEMENT OF OSTEOPOROSIS DURING POSTMENOPAUSE

Luana-Andreea Macovei[1*], Letiția Doina Duceac[2], Elena Rezuș[1]
"Grigore T. Popa" University of Medicine and Pharmacy Iasi

*Corresponding author. E-mail: luanam77@yahoo.com

THE ROLE OF KINESIOTHERAPY IN THE MANAGEMENT OF OSTEOPOROSIS DURING POSTMENOPAUSE (Abstract): Bone functional adaptation is influenced by many risk factors, such as the lack of estrogen during menopause, surgical menopause, premature menopause, a low weight to waist ratio, trauma, excessive alcohol use, tobacco, coffee, certain drugs (corticosteroids, anticonvulsants), food deficiencies (especially low intake of calcium), immobilization, sedentary lifestyle, hereditary and racial factors, various diseases (hyperthyroidism, diabetes). **Material and methods**: The study group included 115 postmenopausal women treated in the 1st Rheumatology Clinic of Clinical Rehabilitation Hospital of Iasi between 1 June 2014 and 31 March 2016. Data gathering, processing and analysis were done by epidemiological, statistical and mathematical methods, using Epi Info 5, a software provided by the Epidemiology Program Office, Centers for Disease Control and the Global Programme on AIDS, World Health Organization. **Results and discussion**: The selection of patients was made based on a diagnosis of established postmenopausal osteoporosis (the diagnosis was made following clinical and radiographic exams and dual energy X-ray bone densitometry). The selected female patients had a bone mineral density (BMD) of less than - 2.5 SDs, dorsal lumbar spine pain and limited joint mobility due to paravertebral muscle contraction. Patients in the study group received kinesiotherapy (local electrotherapy, diadynamic currents, interferential current, etc.). **Conclusions**: Kinesiotherapy was shown to play a major role in rehabilitation, relieving pain, correcting functional disorders of spine (spine mobility, defective spine statics, altered muscle balance), re-educating gait and balance and preventing the risk of falling. **Keywords**: OSTEOPOROSIS, KINESIOTHERAPY, ASSESSMENT, TREATMENT.

Postmenopausal osteoporosis occurs in the first 10 years of lack of menstruation and is caused mainly by estrogen deficiency and other endocrine, metabolic and inherited disorders (1).

Postmenopausal osteoporosis is associated with physiological bone loss (occurring at around the age of 50 years), when women lose approximately 35-40% of cortical bone and 55-60% of trabecular bone, while men lose about 1/3 less (1, 2).

The risk of osteoporosis is mainly determined by two factors: bone mineral density at the beginning of menopause and the speed of bone loss after menopause, dependent on the rate of bone loss and on the years spent in post menopause (3, 4).

The present study aims to standardize an

effective kinesiotherapy program and to assess its effectiveness on bone mineral density, pain, spinal functionality, stability, coordination, balance and gait, and on the quality of life in osteoporosis patients. Paraclinical methods (bone densitometry), clinical analytical methods (joint and muscle assessment), semi global (tests for balance and gait) and global approaches were used (3).

MATERIAL AND METHODS

The study group included 115 postmenopausal women treated in the 1st Rheumatology Clinic of Clinical Rehabilitation Hospital of Iasi between 1 June 2014 and 31 March 2016.

The 115 cases were divided into 4 groups: 16 female patients (13.91%) treated with estroprogestatives, 31 female patients (26.95%) treated with ibandronic acid, 48 female patients (41.75%) treated with alendronic acid and 20 female patients (17.39%) treated with calcium and vitamin D. The results of the therapy were assessed by measuring L4 bone mass density (BMD), the total BMD before the treatment and 2 years after and by comparing T and Z scores at the same time with student's *t*-test. Increases or values of BMD, T and Z scores and the number of female patients who showed an increase or decrease in bone mass density following the four therapeutic approaches were also expressed as a percentage (fig. 1).

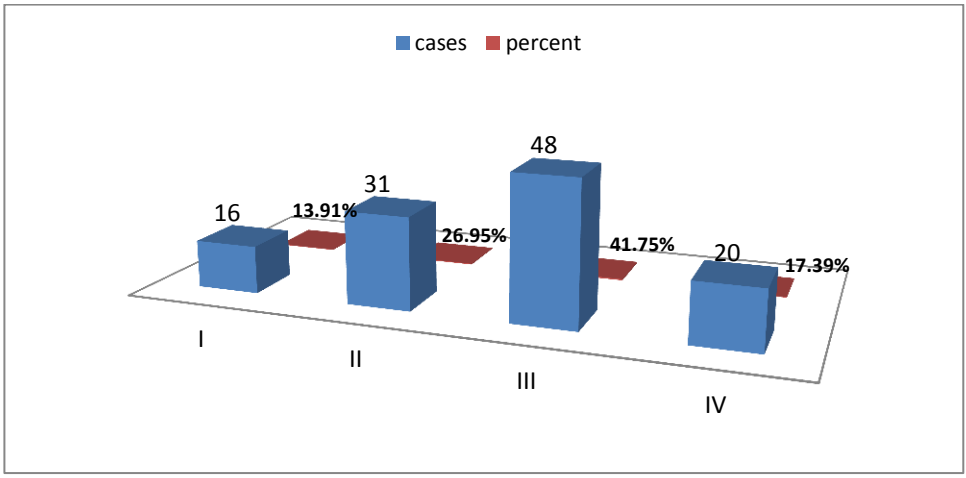

Fig. 1. Distribution of the 115 female patients in the four study groups

RESULTS AND DISCUSSION

According to their residence, most of the female patients were of urban origin (63%) as compared with the female patients of rural origin (37%). This difference is explained by better access to information and medical care in women from urban areas.

The medical history of each female patient provided relevant data for a positive diagnosis of osteoporosis. The patients' history showed major risk factors for osteoporosis.

Five age groups were identified at the beginning of the treatment (under 41 years old, 41-50 years old, 51-60 years old, 61-70 years old and 71-80 years old). The highest number of cases (48, 41.75%) of the group treated with alendronic acid were

found in patients aged between 51 and 60, followed by the age group 61-70. There were more cases in the age group 51 - 60 and 61-70 of the group treated with bisphosphonates. It was found that a slightly younger age of onset was associated with early menopause onset and earlier initiation of therapy.

There is a balance between bone resorption and bone formation in both sexes between the age of 30 and 35. After this age, the bone mass tends to decrease at a rate of 0.5-1% / year. At all ages, women have less bone mass than men, leading to higher rates of osteoporosis and higher risk of fractures with age (5, 6) (tab. I).

TABLE I

Distribution of the four age groups at the beginning of treatment

Age groups (years)	No. of cases	%	Therapy
41-50	16	13.91	Estroprogestatives
51-60	31	26.95	Ibandronic acid
61-70	48	41.75	Alendronic acid
71-80	20	17.39	Calcium and vitamin D

At the beginning of treatment, the patients' age was 31-54, with an average age of 46.67 +/- 7.553 years, but women treated with alendronic acid had the highest average age of onset most advanced (an average age of 61.81 years). This can be explained by the fact that the alendronic acid was administered in cases with lower bone mass density, typically at a T-score of less than -2.5 SDs and most often at a T-score between -3 SDs and -3.5 SDs. Alendronic acid was used as a cure rather than a preventive measure.

The age of first menstruation was not significantly different between the groups treated with calcium and vitamin D, alendronic acid and ibandronic acid; the group treated with estroprogestatives showed a two-point higher average without a plausible explanation.

The age of the last period was significantly lower (an average age of 41.51 years) in the group treated with estroprogestatives. As the age of menopause onset, defined as the age of the last period, was significantly lower in the group of women treated with estroprogestatives, this therapy was favored by patients with early menopause. Younger women accept treatment with estroprogestatives mostly for subjective reasons, including the need to achieve optimal vaginal trophicity and to combat vegetative disorders caused by estrogen deficiency. These patients disregard possible metabolic cardiovascular side effects of estroprogestatives and cancerphobia is less common in this group.

The duration of estrogen deficiency in the four groups cannot be compared with one another. Women treated with estroprogestatives had a duration of estrogen deficiency of 5.13 +/- 4.037 years. This is directly related to the fact that this therapy was administered early after the menopause. The therapy with ibandronic acid was accepted due to the fact that there is no potential risk of inducing estrogen-dependent neoplasia and breast diseases during therapy with estrogen receptor modulators. The alendronic acid was introduced after a long period of estrogen deficiency (15.81 +/- 8.314 years) in women with a severe decrease in bone mass density, but who were generally older. The female pa-

tients with background therapy with calcium and vitamin D were older women who did not agree to hormonal treatments or had a digestive intolerance.

The anthropometric measurements of waist and weight showed close values as average, minimum and maximum. Overweight female patients have a lower exercise capacity, as the excess weight overloads the joints with degenerative changes, leading to various conditions that worsen the health status of female patients. Height is one of the factors that cannot be influenced.

Overweight can aggravate spine deformities and stress the major joints, especially hips and knees. That is why it is important to maintain a healthy weight through a balanced diet and to achieve good muscle tone through regular physical exercise in osteoporosis patients.

The group treated with estroprogestatives had lower height and weight, due to the fact that some patients were suffering from Turner syndrome (reduced height and weight). The study groups treated with calcium and vitamin D, alendronic acid and ibandronic acid were slightly overweight.

Physical activity performed by the patients was mostly moderate, as most women were sedentary and before retirement most of them had sedentary jobs.

Although osteoporosis has a long asymptomatic period, vertebral pain was a common symptom and the main reason for hospitalization.

The required parameters (BMD of the lumbar vertebra = L4 BMD; total BMD; the T-score of the 4th lumbar vertebra - TL4; total T-score - Tt; total Z score - Zt) were used *for analyzing bone mass density*. These parameters have also been investigated at the beginning of the treatment. There was no significant difference between the group treated with calcium and vitamin D and the group treated with estroprogestatives; the group treated with ibandronic acid had a slightly lower L4 BMD; the group receiving alendronic acid had a significantly lower BMD.

Total BMD was correlated with L4 BMD at the beginning of the treatment and it was minimal in the group treated with alendronic acid. It had intermediate values in the group treated with ibandronic acid and the highest averages in the groups receiving calcium and vitamin D, and estroprogestatives, respectively. Women in all study groups had a T-score of less than -2.5 SDs in the L4 vertebra, confirming the diagnosis of osteoporosis. The group treated with alendronic acid had the most severe score (-3.384).

The total T-score at the beginning of the treatment was comparable in the groups treated with estroprogestatives and calcium with vitamin D. It was less severe than in women treated with alendronic acid and ibandronic acid. The correlation between the therapeutic choice and the L4 T-score and the total T-score showed that either alendronic acid or ibandronic acid was preferred when this score showed a higher risk of osteoporosis and a more severe form of osteoporosis (7, 8).

The Z-score shows a negative difference between a subject in the study group and a subject of the same age in terms of bone mass density. It was found that women had a more severe bone mass loss in relation to the average of the same aged female patients as compared with those treated with calcium and vitamin D (7, 9).

It was found that women treated with alendronic acid and ibandronic acid, respectively showed a more severe deficit in BMD in relation to the average of the same aged women as compared with those treated with calcium and vitamin D.

The results showed that the values of the total BMD and of the T-score tend to be lower in patients who are older at the beginning of the treatment. The same applies if the period of estrogen deficiency is prolonged: at the beginning of the treatment, L4 BMD, total BMD and total T are lower when there has been a longer duration of estrogen deficiency.

The results of therapeutic regimens were assessed after two years by analyzing specific parameters. L4 BMD values had a moderate increase in all study groups. The highest increase was found in the group treated with alendronic acid. A low increase occurred in groups receiving calcium and vitamin D, ibandronic acid and estroprogestatives.

The L4 T-score has improved in groups treated with calcium and vitamin D, ibandronic acid and estroprogestatives, with a significant increase in the group treated with alendronic acid. The total T-score has improved in all study groups. The highest increase of the Z-score was found in the group treated with alendronic acid. More moderate increases were seen in the other study groups.

Physical therapy aimed at achieving pain relief, spine mobilization, toning paravertebral muscles, correcting the posture and regaining the ability to exercise.

Local electrotherapy was used for pain relief and for reducing muscle contracture, which is the main cause of pain. The transverse galvanization had an antalgic and anticontractile effect. It is important that the size of the electrodes entirely covers the area to be treated, the intensity of the current fits the threshold and the duration of treatment is long enough (more than 20 minutes).

Diadynamic currents act therapeutically through muscle contractions induced by the excitomotor system. Here too, it is important to adjust the intensity of the current and the duration of treatment for a therapeutic effect.

The interferential current in static and particularly in dynamic mode with excitomotor frequencies is essential in preparing the muscles for the sessions of kinesiotherapy.

Kinesiotherapy is not synonymous with therapeutic exercises. Its scope is more limited, both in terms of resources needed and goals (12).

The use of various exercises, techniques or methods for the functional rehabilitation was based on the knowledge of the functional deficit through a joint and muscle assessment. This provided the angle of movement, muscular endurance and strength, changes in prehension and gait and a thorough physical examination, leading to a scientific validation of the kinesiotherapy protocol.

The efficacy of the rehabilitation treatment and the results were assessed through measurements with goniometer, centimeter and a series of tests that could estimate the range of motion in the damaged joints. Balance and gait were also assessed by using the Tinetti scales.

As in other studies (12), patients in our study groups received the following procedures: re-education of posture and correction of the alignment of body segments (postural disorders of the lumbar spine: kyphosis, lordosis, scoliosis) through self-correcting exercises, muscle stretching for contractured muscle groups, the use of lumbar orthosis, the increase in muscle strength and endurance, improved mobility of lumbar spine through extension exercises, stretching exercises for the muscle groups with a tendency to contraction-retraction: pectoral muscles paravertebral

muscles, the iliopsoas muscles; improvement of balance and coordination; effort training through aerobic exercises, walking, treadmill exercises, ergometer bicycle, jogging, sports, rhythmic gymnastics; respiratory re-education.

Similar to the results in the literature (11, 13, 14, 15) and based on a comparison of data from initial measurements with final measurements and with the control group, we have found a major improvement both in joint range of movement and in muscle strength. The assessment of pain showed a positive outcome both in the control and in the study group.

BMD assessment showed no statistically significant differences compared to the beginning of treatment, but the positive outcome of female patients (joint mobility, muscle strength, improved quality of life, decreased risk of fracture) leads to the conclusion that, even if kinesiotherapy does not replace medication, it may bring significant benefits as additional therapy.

CONCLUSIONS

Our study shows the importance of early detection of risk factors for osteoporosis, as a key element in diagnosing and in adopting a healthy lifestyle.

The results of our study confirm that kinesiotherapy plays a major role in the rehabilitation of patients with postmenopausal osteoporosis, as it relieves pain, it manages spinal functional disorders (spine mobility, defective spine statics, altered muscle balance) and it re-educates gait and balance, preventing the risk of falling.

Rehabilitation and kinesiotherapy must be adapted to each patient, considering individual needs and associated comorbidities; the exercise protocol should be varied, in order to gain patient's interest, adherence and active involvement.

NEWS

SHORT- AND LONG- TERM RESULTS OF RADIAL ARTERY AND SAPHENOUS VEIN GRAFTS IN THE RIGHT CORONARY SYSTEM: A PROPENSITY- MATCHED STUDY

Cardiovascular disease is the leading cause of death worldwide attributed with more than 31% of global deaths (17.5 million people/year) and an estimated 7.4 million deaths due to coronary artery disease (CAD) alone. Coronary artery bypass grafting (CABG) is nowadays one of the most frequent surgical interventions in Europe (between 18 and 91 per 100.000 inhabitants) and according to both European and American societies' guidelines, is associated with an increase in quality of life and survival in patients with unprotected left main (or equivalent) and multi-vessel disease but the ideal grafting technique has not been established. The research group led by dr. Shohei Yoshida aimed to identify the optimal graft for the right coronary territory. Their study evaluated the short- and long-term outcome of radial artery (RA) grafts and saphenous vein grafts (SVGs) to the right coronary artery through propensity score analysis. Superior survival was noted in the unmatched RA group, but after propensity-score matching for late outcomes analysis there were identified 91 patient pairs similar in the two groups. Graft failure did not correlate with overall mortality, but displayed a strong correlation with cardiac events in all patients (RA and SVG). The predictors of graft occlusion in the RA group were mild proximal stenosis and low indexing glomerular filtration rates for body surface area, whereas those in the SVG were female gender and off-pump coronary artery bypass grafting. The authors concluded that there were no significant differences in long-term outcomes between the RA and SVG groups but predictors of graft occlusion differed between the two groups. Renal dysfunction in particular impaired RA patency, emphasizing the importance of careful graft selection for preventing long-term cardiac events. ETHIOPATOGENIC HYPOTHESES IN LICHEN PLANUS (Abstract): Lichen planus is a mucocutaneous inflammatory dermatosis characterized by a papular rash; the disease is self-limited, has several clinical subtypes and follows a chronic or subacute clinical course. This article presents some etiological hypotheses: stress, genetic predisposition, systemic diseases, viral infections, materials used in dentistry. Also, medicines or contact allergens can cause lichenoid reactions, which are the main differential diagnosis. Autoimmune hypothesis can be supported by the association with other autoimmune diseases, such as ulcerative colitis, alopecia areata, vitiligo, dermatomyositis, morphea, lichen sclerosus, myasthenia gravis. This disease seems to be mediated through an antigenic mechanism of cytotoxic T lymphocyte activation, and production of proinflammatory cytokines, cascade of events that causes apoptosis of basal keratinocytes. A good understanding of the pathogenesis, clinical presentation and early diagnosis of lichen planus is critical in determining the appropriate therapeutic management. This present article aims to present and discuss the various etiopathogenetic concepts of lichen planus. **Keywords**: LICHEN PLANUS, ETIOLOGY, PATHOGENESIS.

Lichen planus is a noncontagious pruritic, papular inflammatory dermatosis of unknown etiology mainly affecting middle-aged adults (1).

The term "lichenoid" is used by clinicians to describe a flat-topped, glossy, papular lesion resembling lichen planus, or by histopathologists to describe a type of tissue reaction mainly consisting of basal cell liquefaction and an infiltrate of inflammatory cells that fills the papillary dermis in a band-like fashion. The name of lichen refers to the rough, dry appearance similar to that of lichens (symbiotes, fungi/algae that grow on the bark of trees) of the affected skin (1).

Lichen planus has different clinical subtypes based on lesion morphology and involved region. It can affect the skin, mucous membranes and skin appendages. Skin lesions are classically described by the 5 "Ps": papules, planar, polygonal, purple, pruritic, mainly located on the flexor aspects of the forearms, dorsal surface of the hands, lumbar region, ankles and genitally in males (2). At mucosal level, reticular,

papular lesions, erosive, atrophic or bullous plaques can be seen (3). Nail changes consist in onychorrhexis, onycholysis, onychoschisis, anonychia, trachyonychia, irregular depressions, subungual hyperkeratosis, and pterygium (4). On the scalp, it may cause scarring alopecia (5). Wickham striae (fine, lace-like network of white lines and points) can be spotted on the surface of the lesions. The linear configuration of lesions suggests they were induced by scratching (Köbner sign) (2).

The etiopathogenesis of lichen planus is still uncertain, but some evidence reveal that the disease is an immune process triggered by an antigen that alters the keratinocytes in the basal layer, making them susceptible to cell immune response. It induces the activation of CD4 + and CD8 + T lymphocytes, production of pro-inflammatory cytokines, such as interleukin-2 (IL2), interferon-gamma (IFN-gamma), tumor necrosis factor (TNF), cascade of events that causes basal keratinocyte apoptosis and rupture of basement membrane. The antigen responsible for inducing the immune response is still unknown, and its intrinsic or extrinsic origin is a matter of controversy. In some situations, especially in oral lichen planus, certain extrinsic antigens, included in the substances used in dental practice, dental amalgams, medicines (especially antimalarials, agents used in cardiovascular diseases, gold salts, non-steroidal, anti-inflammatory drugs and hypoglycemic agents) were identified. In such cases, although the lesions are very similar clinically and histologically to the idiopathic lesions, a lichenoid reaction is the preferred term. Thus, history and physical examination should also aim at establishing a cause-effect relationship in the pathogenesis of the disease (6).

ETIOLOGIC FACTORS

Genetic predisposition

The reported incidence of familial lichen planus varies widely in the literature and ranges from 1% to 15% for all forms of lichen planus. Genetic predisposition may influence the mucocutaneous reactivity to etiological factors. Genetic polymorphism of some HLA markers (especially HLA-A3, HLA-DR1, HLA-DQ1) as well as of some inflammatory cytokines, have been associated with the presence of lichen planus. Familial lichen planus is characterized by early onset and development of atypical forms with mucosal involvement. The lesions are recurrent and do not respond immediately to treatment (4).

Environmental factors

1. *Infectious factor*. The increased prevalence of liver disease among patients with lichen planus is still debated. Recent studies suggest testing for hepatitis C virus markers, especially in oral erosive lichen planus. Seroprevalence of hepatitis C in patients with lichen is up to 25%, while in the general population is about 5%. The prevalence of lichen planus in chronic hepatitis C is 5% and 1% in the general population. In 21-34% of lichen planus patient's liver function is impaired (7).

Recent studies developed in Mediterranean populations, United States, Saudi Arabia, Taiwan and Nigeria have confirmed the link between hepatitis C virus (HCV) infection and lichen planus, especially the oral form. This association can be explained by the ability of HCV to infect cells other than hepatocytes, epidermal cells, respectively, and by the frequent mutations of the virus that cause repeated activation of immune cells, increasing the risk of autoimmune diseases. In addition, treatment with interferon gamma (INF-

gamma) administered to hepatitis patients may account for lichenoid eruptions. It seems that oral lichen planus associated to HCV infection is a distinct subtype, several studies reporting a much higher frequency of a HLA-II allele, namely HLA-DR6 compared with patients with oral lichen planus without HCV infection (7).

Several viral infections have been associated with oral lichen planus, particularly those of the herpes virus family: herpes simplex, Epstein-Barr virus, cytomegalovirus and herpes virus 6. But there are still doubts whether these agents are responsible for the occurrence of lichen planus or cause a superinfection of preexisting lesions. The best investigated virus, after HCV, was the human papillomavirus (HPV). Syrjanen S et al. show a strong link between HPV and oral lichen planus. Moreover, HPV prevalence gradually increases with severity of lesions, and may also be associated with progression to malignancy. On the other hand, ulcerated lesions are believed to increase the risk of HPV infection and chronic corticosteroid treatment may favor virus replication. Thus, it is unlikely that the isolated presence of the virus to trigger the disease, but it may aggravate or favor the lesions and increase the risk of malignant transformation (8).

Recently, it has been suggested that *Helicobacter pylori* is involved in the etiology of lichen planus. During a duodenal ulcer or gastritis, *Helicobacter pylori* induces a significantly increased secretion of interleukin 1-beta and TGF-beta, cytokine involved in the pathogenesis of lichen planus. Eradication of *Helicobacter pylori* infection can result in the improvement of lichen lesions (3).

2. *Endogenous antigens.* Of the involved endogenous antigens, heat shock proteins are the ones that stand out. They are expressed by all types of cells and play a role in intercellular communication, cell differentiation and growth, signal transduction and apoptosis. Increased expression of these proteins may be in response to multiple exogenous agents such as sudden temperature changes, medications, viruses, nutritional deficiencies and growth factors. In oral lichen planus, this protein is expressed in large amounts, suggesting that it may be an autoantigen of the disease. Identification of an autoantigen associated with the other disease features, such as chronicity, association with other autoimmune diseases, preference for female gender, presence of T lymphocytes in lesions and resolution after the administration of immunosuppressive treatment, represents the full picture of autoimmune theory. However, as shown above, heat shock protein overexpression may occur because of multiple exogenous agents, representing an intermediate step and not the causal factor (9).

3. *Vaccines*. Various cases of lichen planus following HBV (hepatic B virus) vaccination have been reported. The interval between the administration of the initial vaccine dose and the development of lichen planus lesions ranges from a few days to 5 months. In a study of 18 pediatric patients, 5 developed bullous lichen planus after vaccine administration. It is possible that T lymphocytes formed following vaccine administration to cross-react with different epitopes expressed on keratinocytes. Patients who develop lichen planus are recommended to discontinue vaccination schedules due to the increased risk of developing severe lichen planus lesions (10).

4. *Neuropsychiatric factor.* Neuropsychiatric disturbances, such as depression, anxiety and stress were investigated in the etiology of lichen planus, the patients re-

porting the onset or exacerbation of lesions during high emotional stress conditions. Studies on this topic are quite controversial. Girardi C et al found a positive association between lichen planus and emotional states, while others did not. The use of different questionnaires, subjectivity and lack of standardization between studies are responsible for the controversial results. The pathology being complex, it is obviously the result of the interaction of multiple factors. It is likely that stressful situations influence the course of disease, by the alteration of immune functions and Th1/Th2 cytokine balance with increased Th2 response (11).

5. *Medications.* Numerous drugs are involved in the occurrence of cutaneous mucosal lichenoid eruptions and/or of the mucous membranes, especially of the oral ones. Sometimes, lichenoid reactions can be located only on genital mucosa. We emphasize that lichenoid reactions occur after a latency period of several months to years, unlike most drugs side effects which occur after a short period of treatment (12).

The mechanism by which drugs induce lichenoid reactions (tab. I) is unknown, the most plausible theory being that they occur following the cytotoxic T cell-mediated immune response against a Class 2 MHC antigen complex/drug, so that keratinocytes and Langerhans cells are seen by the immune system as "non-self". Macrophage migration inhibitory factor is significantly increased (12).

TABLE I

Medications causing lichenoid reactions (13)

Cutaneous reactions	Mucosal eruptions
Antimalarials	Gold salts
Gold salts	Nonsteroidal anti-inflammatory drugs
Isoniazid	Ketoconazole
Beta-blockers	D-penicillamine
Piritinol	Methyldopa
Thiazide diuretics	Sulphonyl urea
Levamisole	Allopurinol
Captopril	Inhibitors of angiotensin converting enzyme
Lithium carbonate	
Phenothiazines (Metopromazine, Levomepromazine)	
Methyldopa	
Antimitotic drugs (Hydroxyurea, Methotrexate)	
D-penicillamine	
Phenylenediamine salts	

6. *Color film developing agents and methacrylic acids.* Lichenoid eruptions have been reported in almost 25% of the people exposed to chemicals in color film developing agents. The responsible chemicals are the paraphenylenediamines. The current automatic film processors minimize the contact with these chemicals, this type of lichenoid eruptions being rare today. There have been reports of lichenoid eruptions in workers exposed to methacrylic acid used in the automotive industry. Also, because dental devices also contain methacrylic acids, they could be considered causative factors in oral lichen planus. Other materials that could induce lichenoid

reactions are dental materials, nickel, and gold aminoglycoside antibiotics (12).

7. *Dental fillings*, especially the mercury in the dental filling materials. Between 87 and 97% of the patients with oral lichen planus associated with dental fillings experienced improvements after dental filling removal, but only 28-39% of these patients had positive patch test to mercury. Patients who experienced improvements after amalgam removal but negative patch tests were supposed to have allergic reactions to dental fillings. A recent study reported that not the presence of fillings or gold is associated with a higher risk of oral lichen planus, but rather filling corrosion and a galvanic effect by the dissemination of metals in direct contact with oral mucosa (9).

8. *Graft-versus-host reaction*. Cutaneous Graft-Versus-Host Reaction (cGVHR) includes all inflammatory manifestations that may arise at variable intervals after transplantation of an organ containing lymphoid cells. Chronologically there:

- acute graft-versus-host reaction- occurs after 7-21 days and is mainly induced by donor's mature T lymphocytes; the main clinical manifestation is macula-papular exanthema;
- chronic graft-versus-host reaction- it may be an extension of acute form of may occur de novo. The average onset is after 4 months but it may also develop after day 40. Both donor's T cells and autoimmunity are involved. The cutaneous manifestations consist in lichenoid and/or sclerodermiform eruptions. Erythroderma and fasciitis are rare manifestations (3).

PATHOGENETIC MECHANISMS

The intimate etiopathogenetic mechanisms on lichen planus are not fully elucidated. Recent data suggest that lichen planus is a cell-mediated autoimmune disease, hypothesis supported by its possible association with other autoimmune diseases: primary biliary cirrhosis, chronic active hepatitis, Gougerot-Sjogren syndrome, dermatomyositis, lupus erythematosus, morphea, vitiligo, alopecia areata, autoimmune thyroid disorders, ulcerative colitis, myasthenia gravis, Biermer anemia, Addison's disease. Vesicular forms can coexist with certain cancers (6).

Multiple cell types, extracellular matrix proteins and chemokines, contribute in different ways to the development of lichen planus. The presence of the cells that induce T lymphocyte migration and activation and keratinocyte destruction triggers a cell-mediated antigen-specific immune response. On the other hand, metalloproteinases, chemokines and mast cells are responsible for the non-specific immune response. Finally, anti-desmoglein 1 and 3 circulating antibodies, along with the identification of immunoglobulin (Ig) M and IgA in the lesion suggest that humoral immunity plays a role in the pathogenesis of lichen planus (6).

The cells involved in the pathogenesis of lichen planus are: keratinocytes, CD4+ helper lymphocytes, CD8+ cytotoxic lymphocytes, dendritic cells, mast cells and macrophages, their levels varying per lesion stage. In the early stages, the levels of helper T lymphocytes, macrophages and dendritic cells are higher than in more advanced lesions, the key role being played by suppressor T cells. This distribution suggests that in the initial stages antigen-presenting cells as well as the cells responsible for the induction of the inflammatory response are the predominant cell population, while suppressor cells appear in more advanced stages, causing keratinocyte apoptosis (6).

Keratinocytes, cells that form the epithelium, are responsible for the secretion of type IV collagen and laminin 5, major structural proteins in the basement membrane, which in its turn is essential for maintaining keratinocyte viability, with dependence and close relationship between these two. In lichen planus, the keratinocyte is the target cell, the cell that undergoes apoptosis. For this phenomenon to occur, the cell must present an antigen (still unknown) since the onset of the pathogenic process. Once activated, keratinocytes secrete chemokines, which attract lymphocytes and other immune cells and trigger the pathogenic mechanism and favor the chronic nature of the disease (9).

Dendritic cells play an important role in immune response, activating T lymphocytes by antigenic stimulation. Studies show an elevated number of dendritic cells in lichen planus, especially Langerhans cells, stromal and plasmacytoid dendritic cells, with a role in promoting the inflammatory response. Of these, Langerhans cells have been most extensively studied. They are in the upper basal layer of the epithelium higher, and their function is to capture antigens. When this process takes place, the cells are activated, migrate to regional lymph nodes and activate T lymphocytes, eliciting a primary immune response. When Langerhans cells recapture the same antigen, they will be recognized by memory T lymphocytes, which will induce a secondary immune response. In lichen planus lesions, large numbers of Langerhans cells are present in the basal layer of the epidermis. It is assumed that they present antigens to T lymphocytes by molecules of the major histocompatibility complex class II (MHC class II), generating both an initial sensitivity to that antigen (primary immune response) and a secondary immune response leading to the occurrence of clinical signs (14).

CD4+ T lymphocytes are cells able of activating B lymphocytes, macrophages and CD8+ T lymphocytes, thus being responsible for the recruitment of various cells involved in the immune response. CD4+ T lymphocytes are classified into three subtypes: Th1 (lymphocytes T helper), Th2 and Th17, morphologically indistinct, but distinct by the cytokines they secrete. Th1 subtype is characterized by the production of IFN-gamma, IL-2 and TNF-alpha, cytokines which activate macrophages and cytotoxic T lymphocytes. Th2 subtype secretes IL-4, IL-5, IL-10 and IL-13, crucial for antibody production. The recently discovered LT Th17 produce IL-17, IL-22 and IL-26. IL-17, with an important role in the inflammatory response, is also associated with other autoimmune conditions, such as multiple sclerosis, psoriasis, and lupus. The number of Th1 and Th17 cells and IL-17 serum level were significantly increased in patients with lichen planus compared to the control group, especially in oral atrophic-erosive lichen planus, suggesting that Th17 and IL-17 may play important roles in the pathogenesis of lichen planus, especially in the oral type. CD4+T lymphocytes attach as a sub epithelial band in the lamina propria. However, they are not present near the basement membrane rupture. CD4+ T lymphocytes are activated by MHC class II antigens presented by the Langerhans cells or keratinocytes. From this moment on, LT CD4+ activates the cytotoxic T lymphocytes through binding of RCA (Request to Cytotoxic Activity) the receptor on the surface of CD8+ T lymphocyte, or secretion of Th1 cytokines, such as IFN-gamma, IL-2 and TNF-alpha. In addition, local production of

IFN-gamma maintains keratinocyte MHC class II expression, contributing to the chronicity of lesion (15).

In lichen planus, CD8+ T lymphocyte infiltrate is located primarily intraepithelial near basement membrane rupture. Keratinocytes are destroyed in several ways: by activation of perforins and granzymes or by expression of FasL receptor (CD95), which interacts with the Fas molecule on the surface of keratinocytes, or by secretion of TNF-alpha, which causes apoptosis by binding to TNF receptor on keratinocyte (6).

Mast cells can activate T lymphocytes and to produce several mediators which modulate the inflammatory response. In lichen planus, there is an increase in mast cell density in the lamina propria, near blood vessels and nerves, and especially near the basement membrane rupture, suggesting that it might play a direct role in the basement membrane destruction and intraepithelial migration of CD8+T lymphocytes. Mast cells also releases a series of cytokines, such as IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-16, TNF-alpha and Regulated on Activation, Normal T Cell Expressed and Secreted (RANTES), through which, by a cyclic mechanism an interaction between T-lymphocytes and mast cells is established, interaction that may maintain the chronicity of inflammation (6).

Immunofluorescence studies also reveal the involvement of humoral immunity, globular IgM (occasionally IgG and IgA) deposits, corresponding to colloid bodies, being discovered. Also in support of a humoral autoimmune mechanism comes the finding of high serum level of anti-desmoglein 1 and 3 autoantibodies in patients with oral erosive lichen planus compared with patients with reticular lichen planus or recurrent thrushes. Of course, the increased level of these autoantibodies could be the consequence of the erosive nature of lichen planus (6).

Other researches show that the TNF-alpha serum level is significantly elevated in lichen planus patients. Also noted was the increase of metalloproteinases MMP-1 and 3 in patients with oral erosive lichen planus, these two being involved in the induction of apoptosis and basement membrane degradation (6).

CONCLUSIONS

We observed that to understand the ethipathogenic mechanisms of lichen planus, recognize its clinical subtypes and differentiate it from other diseases is of critical importance. The interaction of various factors is responsible for the initiation, persistence and worsening of lichen planus lesions. So, given the multifactorial nature of lichen planus, an accurate early diagnosis is essential for an adequate therapeutic approach.

A HIGHLY DURABLE RNAi THERAPEUTIC INHIBITOR OF PCSK9

Proprotein convertase subtilisin-kexin type 9 (PCSK9) is known as a target for LDL cholesterol-lowering therapy. Inclisiran is a long-acting RNA interference (RNAi) therapeutic agent, subcutaneously delivered, that inhibits the synthesis of PCSK9. In a study by Fitzgerald *et al.* healthy volunteers received a subcutaneous injection of inclisiran or placebo in either a single-ascending-dose phase (at a dose of 25, 100, 300, 500, or 800 mg) or a multiple-dose phase (125 mg weekly for four doses, 250 mg every other week for two doses, or 300 or 500 mg monthly for two doses, with or without concurrent statin therapy). It was showed that the reported adverse events (cough, musculoskeletal pain, nasopharyngitis, headache, back pain, diarrhea) were mild or moderate. Inclisiran doses of 300 mg or more reduced the PCSK9 level, and doses of 100 mg or more reduced the LDL cholesterol level in the single-dose phase. Reductions in the levels of PCSK9 and LDL cholesterol were maintained at day 180 for doses of 300 mg or more. All multiple-dose regimens reduced the levels of PCSK9 and LDL cholesterol. The study concluded that no serious adverse events were observed with inclisiran and doses of 300 mg or more significantly reduced levels of PCSK9 and LDL cholesterol for at least 6 months (Fitzgerald K, White S, Borodovsky A, et al. A Highly Durable RNAi Therapeutic Inhibitor of PCSK9. *New England Journal of Medicine* 2016, DOI: 10.1056/NEJMoa1609243).

INTERRELATIONSHIP BETWEEN PATHOPHYSIOLOGICAL MECHANISMS OF VITAMIN D DEFICIT AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE (Abstract): Several similarities have reported between patients with suboptimal level of vitamin D and patients with Chronic Obstructive Pulmonary Disease (COPD): both conditions are more prevalent after the 6th decade and are associated with impaired defense mechanisms, with skeletal muscles dysfunction and with an early ageing process. We have reviewed the literature concerning the interrelationship between the main pathophysiological processes of both conditions, in order to emphasize the influence of vitamin D deficit on COPD development and evolution. Epidemiological, clinical and experimental data supporting this association are presented. We concluded that the identification of common pathophysiological mechanisms for the vitamin D deficiency and COPD substantiates the hypothesis of the involvement of this hormone in the chronic obstructive pulmonary disease. **Keywords**: VITAMIN D, COPD, PATHOPHYSIOLOGICAL MECHANISMS.

Vitamin D is well-known for its essential role in bone metabolism. Nevertheless, the perspective on vitamin D has changed significantly over the past years and new actions have been described. The activation of vitamin D takes place in the tissues which express 1-α-hydroxylase (CYP27B1), an enzyme that is present, beside other localizations in the pulmonary cells, striated muscles (including the respiratory muscles), endothelium and in the cells involved in the processes of specific and non-specific defense (1). Several similarities have been noticed between adults with suboptimal level of vitamin D and Chronic Obstructive Pulmonary Disease (COPD). Both conditions mostly affect adults over 60 years old. The suboptimal level of vitamin D has 59 % prevalence in Romania, with a peak in elderly females (2). In cer-

tain risk groups, such as people with osteoporosis, the level can reach over 80% (3). The estimated prevalence of COPD in Romania is 8.3% and is higher in males aged over 60 (4). The level of vitamin D has seasonal variation and reaches its peak in the cold season, when there are also the most frequent exacerbations of COPD. A recent meta-analysis showed that low levels of vitamin D correlate with the COPD severity (6) and is associated with a decrease of the ventilatory function, irrespective of other factors (5).

IMPAIRMENT OF THE DEFENSE MECHANISMS

Impairment of the non-specific inflammatory response is a classical pathophysiological mechanism of COPD, which relates to the chronic inhalation of irritants that activates the pattern recognition receptors, such as Toll-like receptors and increases the transcription nuclear factor kB (NF-kB) and of the mitogen-activated protein kinases (MAPK) in the pulmonary neutrophils and macrophages. The chronic inflammatory processes and the oxidative stress lead to mucus hypersecretion, destruction of the elastin fibers and fibrosis.

Vitamin D suppresses in macrophages the formation of inflammasome by preventing the activation of the TLR-NF-kB pathway by the bacterial endotoxins. It also increases the IL10 production by enhancing transcription and via a calcium-dependent mechanism (7, 8). Vitamin D inhibits the maturation of dendritic cells, which modulates the function of T helper cells (Th), increasing the efficiency of the defense mechanism. Therefore, in vitamin D deficit, there is an impairment of the nonspecific host defense with increase of the inflammatory processes and a decrease of the reparatory, limitative ones. Vitamin D (1.25-dihydroxyvitamin D3) receptors (VDR) complex translocate in the nucleus, inducing the expression of *cathelicidin*, an antimicrobial and anti-inflammtory peptide. Cathelicidin is expressed in cells involved in the primary line of defense (keratinocytes, leukocytes, monocytes, neutrophils) as well as in T and B or NK cells.

In macrophages, the activation of Toll-like receptors up regulates the expression of VDR and of the genes expressing 25(OH)D3-1α-hydroxylases, inducing the expression of cathelicidin and the intracellular destruction of Mycobacterium tuberculosis (9, 10). In aseptic inflammation, cathelicidin plays a role in chemokine expression, stimulates angiogenesis and apoptosis and favors wound healing (10). Therefore, the chronic bacterial colonization and the decrease of the defense ability against pathogens through an impairment of the macrophage and neutrophils function in COPD patients could be magnified by the low level of cathelicidin secondary to vitamin D deficiency.

The actual mechanism of the specific immunity activation in COPD is not known. An exacerbated immune activation is noted, along with the increase in the number of T lymphocytes (L) and BL in the lungs. Lymphocytes organize themselves in lymphoid follicles, with the increase of the number and the activation of dendritic cells, which induces a predominantly differentiation in Th1 type. This increases the level of TNF-α, IL-1β, and IL-6, cytokines with pro-inflammatory effect, of the TGF-β and other growth factors for fibroblasts. These processes end up with the fibrosis of the small airways and a permanent inflammatory infiltrate of monocytes and Th1 cells. Vitamin D suppresses

both the proliferation and the secretion of pro-inflammatory Th1 cytokines: IL2, IFNγ, TNFα and promotes the synthesis of anti-inflammatory cytokines by Th2 lymphocytes (IL3, IL4, IL5, IL10) (10, 11, 12). As consequence, in vitamin D deficit, the pathogenic mechanisms of COPD, previously described, are favored (fig. 1).

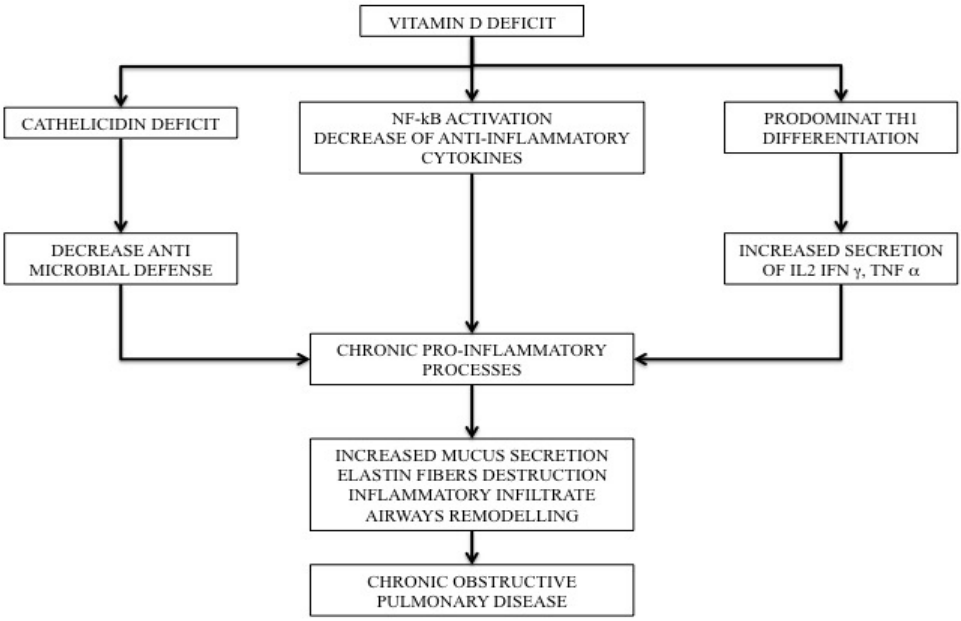

Fig. 1. Defense mechanism impairment in vitamin D deficit and COPD

THE DYSFUNCTION OF THE RESPIRATORY MUSCLES

The respiratory muscles are made up of 2 very thin muscle layers located in the intercostal space and by the diaphragm; the contraction of the later one ensures 70% of the ventilation/minute. In COPD, hyperinflation causes the flattening of the diaphragm and reduces the contraction force by altering its radius; hyperinflation also changes the normal relationship between the ends of the myosin fibers and the actin filaments and decreases the pressure generated for the same tension developed within (13). As an adaptation to permanent overload, type II fibers in the respiratory muscles change into type I fibers (14, 15), increasing the diaphragm resistance to fatigue but decreasing its ability to generate contraction force. In COPD, there is also a reduction in number and length of sarcomeres that moves the curve tension length to the left, as an adaptation to a lesser inspiratory extension determined by hyperinflation. However, reduction of the number of sarcomeres will end up reducing the force of muscle contraction. The respiratory muscles have to work 10 – 14 times more in COPD patients, as compared to healthy people, due to the chronic hypoxemia (16) and the adaptive phenomena described so far become inefficient. Even in moderate forms of COPD, the force of the inspiratory muscles is more severely

reduced than that of the expiratory ones; this is associated with a decrease of the proximal muscle force in the peripheral muscles (17). The long-term effects of COPD on respiratory muscle are muscle atrophy, changes in titin structure and an increase of sarcomere susceptibility to the harmful action of external factors (18).

Vitamin D has a regulatory role in muscle development and in the contraction force, increasing the transcription of myosin and of other calcium binding proteins. The association between the vitamin D deficiency and the proximal myopathy is clinically demonstrated by the improvement of muscular force after the administration of vitamin D to adults with a deficit of this vitamin. The preferential atrophy of type II muscle fibers may occur in the vitamin D deficiency with a similar effect to the one found in age-related sarcopenia and COPD (19) and it is reversible after vitamin D administration (20). The interaction of vitamin D with VDR stimulates adenylate cyclase, phospholipase C, D and A2 and increases the MAPK signal and inositol 3 phosphates (IP3). The intracellular calcium rises by influx through calcium voltage-dependent channels activated by proteinkinase A and by release from endoplasmic reticulum system IP3. The MAPK and Akt signal influences cell development, mitosis and differentiation of the myoblasts. Vitamin D deficiency will trigger a reduction of the contraction force through calcium deficit and impaired muscle fibers formation (21) and a decrease of the phosphate transport into the muscle cell, essential for ATP and protein synthesis.

Vitamin D releases the arachidonic acid from the phosphatidylcholine bound to the cell membrane. This polyunsaturated fatty acid modulates the insulin receptors and the glucose uptake (22, 23). Reduction of glucose transport in muscle cell under low level of vitamin D condition has major metabolic implications and reduces the ATP production, contributing to the reduction of the contraction force (fig. 2).

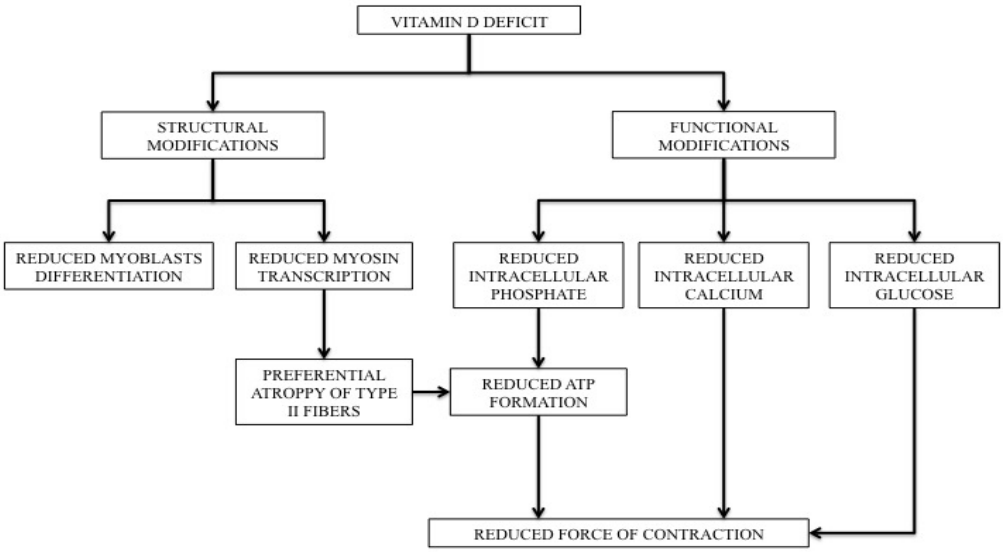

Fig. 2. Reduction of the contraction force of the respiratory muscles in vitamin D deficit

THE PREMATURE AGEING PROCESS OF THE CELLS IN THE BRONCHIAL MUCOSA

Forced expiratory volume in one second **(**FEV_1) normally decreases with age from a peak reached around 25 years old. Patients with COPD present an accelerated yearly decrease of FEV_1, generally fewer than 60% of the value corresponding to age (24). Subjects who reach a maximum of initial FEV_1 lower than the medium one may develop symptoms even if no other risk factors are present, through the normal age reduction of the pulmonary function. Genetic factors, reduced physical activity during childhood/adolescence, treatment with glucocorticoids and malnutrition are other possible causes of low initial maximum FEV_1.

The premature ageing process in COPD is related to the reduction of the expression of sirtuins compared to the age. Oxidative stress, characteristic for the chronic inflammation in COPD, blocks sirtuins activity. Vitamin D also affects both the acetylation of histones and the methylation of the DNA. The VDR/RXR complex, in the absence of 1.25-D3, can bind to co-repressors which attract histone-deacetylases. By binding of vitamin D to VDR, the co-repressors are replaced by co-activators as histone acetyl transferases; these might lead to similar effects with the decrease or blockage of the sirtuins.

The decrease of autophagy and the increase of mitophagy contribute to premature ageing of the respiratory mucosa in COPD. The mitophagy, enhanced by many compounds from the cigarette smoke, has the opposing effect to autophagy, triggering apoptosis. Vitamin D takes part in the regulation of autophagy through calcium, PI3k, the expression of becline-1 (25, 26) and of cathelicidin (27). In the absence of vitamin D, the physiologic processes of autophagy are reduced and the cell destruction phenomena are emphasized (25, 26).

The level of vitamin D decreases after the 6th decade. A conclusion regarding the preventive effect of vitamin D on the ageing of bronchial cells in COPD, although conceivable, has not yet enough scientific proofs.

CONCLUSIONS

We concluded that the vitamin D and COPD relationship is very complex. Since the epidemiologic and experimental data support the relationship between vitamin D deficiency and COPD, it is expected that future research will bring important insights in the understanding of these processes. The identification of common pathophysiological mechanisms for the vitamin D deficiency and COPD substantiates the hypothesis of the involvement of this hormone in the chronic obstructive pulmonary disease.

SCORING IN ACUTE PANCREATITIS: WHEN IMAGING IS APPROPRIATE? (Abstract). Acute pancreatitis (AP) is a frequent presentation to the emergency departments with a rising incidence and a great variability in clinical severity and outcome. The aim of this review is to offer a succinct presentation on acute pancreatitis scoring systems and the use of different imaging methods in severity prediction: Ranson criteria, Glasgow criteria, Hong Kong Score, Acute Physiology and Chronic Health Evaluation II (APACHE II), computed tomography scoring systems, Bedside Index of Severity in Acute Pancreatitis (BISAP) score, Panc 3, Japanese Severity Score (JSS), Harmless Acute Pancreatitis Score (HAPS), Pancreatitis Outcome Prediction (POP), Sequential Organ Failure Assessment (SOFA). This article also describes the Revised Atlanta Classification of AP (2012) and the correlation with computed tomography. **Keywords:** PANCREAS, SCORING SYSTEM, PROGNOSIS

Acute pancreatitis (AP) is defined as an acute inflammatory disease of the pancreas which may involve the peripancreatic tissue and remote organ systems (1). The incidence of AP ranges in different studies from 13 to 45 per 100,000 (2). AP can result in a systemic inflammatory response syndrome with significant morbidity and mortality in 15-20% of patients (3, 4). The most common causes of acute pancreatitis are gallstones, idiopathic and alcohol; occult microlithiasisis probably the main cause of idiopathic pancreatitis (5,6).

Most patients present a mild and self-limiting disease (80-85%), and the remaining ones develop complications (major local or systemic), which lead to multiple organ failure and death. The mortality rate for the severe form of AP (SAP) is high, up to 30% (7). The possibility of selecting patients with SAP is pivotal for proper treatment, observing closely the course of disease and relying on clinical decision-making.

REVISED ATLANTA CLASSIFICATION

The *revised Atlanta classification* (11) divides AP into interstitial edematous pancreatitis and necrotizing pancreatitis, each with an early phase (1st week) and a late phase (after 1st week). Characteristically, the early phase of treatment is based on clinical parameters and in the late phase of treatment decisions are made by a combination of clinical parameters and morphologic criteria (peripancreatic fluid collections, pancreatic necrosis, other complications) established on the basis of computed tomographic (CT) findings (10).

Contrast-enhanced CT is the primary tool for assessing the morphologic criteria and is suited for patients who develop or are likely to develop SAP. The ideal time to visualize complications of AP with CT is 72 hours after the onset of symptoms.

In the revised Atlanta classification (11), necrotizing pancreatitis is subdivided into parenchymal necrosis alone, peripancreatic necrosis alone and a combined type (parenchymal and peripancreatic necrosis). The terminology for fluid collections is also revised, designated as acute peripancreatic fluid collection and acute necrotic collection within the first 4 weeks, and in pancreatic pseudocyst and walled-off necrosis after 4 weeks, respectively (fig. 1, 2).

The revised Atlanta classification (11) is not necessarily a predictor of severity, but it classifies disease severity based upon clinical and imaging features.

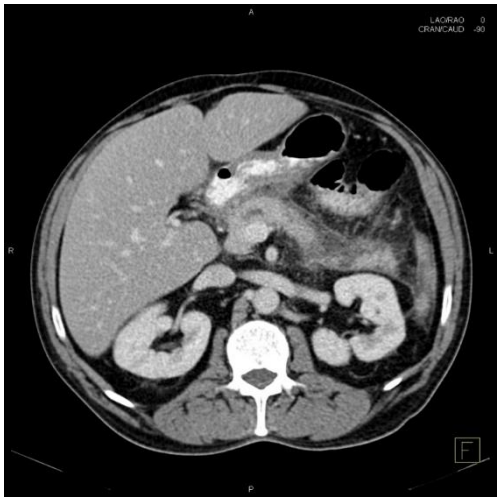

Fig. 1. Contrast-enhanced CT scan in a patient with interstitial edematous acute pancreatitis developing an acute peripancreatic fluid collection around body and tail (Collection of Radiology and Medical Imaging Laboratory, Iaşi"Sf. Spiridon" University Hospital, Prof. dr. D. Negru).

PROGNOSTIC SCORING SYSTEMS

The correct identification of SAP only by clinical assessment on admission is reported in 40-64% of patients. The requirement for an early objective measure of AP severity was recognized in the mid ′70s by Ranson who established the characteristics of the ideal prognostic method: objectivity, accuracy, simplicity, availability at diagnosis, non-invasiveness, quantitativeness, independence with regard to etiology and pre-existing disease, complication specificity, usefulness for disease course monitoring (13).

Fig. 2. Contrast-enhanced CT scan in a patient with acute necrotic pancreatitis, in late phase (after 4 weeks), with a pancreatic and peripancreatic fluid collection which meets the criteria for walled-off necrosis (inhomogeneous content, well defined wall). (Collection of Radiology and Medical Imaging Laboratory, Iaşi "Sf. Spiridon" University Hospital, Prof. dr. D. Negru).

Prognostic assessment by means of single laboratory markers is easier to use than scoring systems which are often difficult to apply and have a high degree of complexi-

ty. There are many analyses used in the prognostic evaluation of patients with AP (e.g. amylase, calcium, white blood cell count, blood glucose, hematocrit, phospholipase A2, coagulation factors, polymorphonuclear elastase, arterial hypoxemia, acidosis, ribonuclease, endothoxin, trypsinogen activator peptide, pancreatitis-associated peptide, neopterin, interleukin 6, interleukin 8, C-reactive protein (CRP), procalcitonin, creatinine, blood urea nitrogen -BUN) without confirmation of their validity. CRP usually peaks 72 hours after the onset of symptoms, at the end of therapeutic window, but it is an important marker for necrosis. BUN elevation on admission or rising 24 hours after the onset is associated with higher mortality (14).

Numerous *multifactorial prognostic scoring systems* (15, 16) have been proposed in the last 40 years, incorporating physiologic, laboratory, imaging parameters, performing with moderate sensitivity and high negative predictive value; also the positive predictive value is suboptimal, but there are debates regarding the design for initial and sequential studies, many studies that have used or assessed these scoring systems having limitations due to the small number of enrolled patients with SAP.

Ranson criteria (18) are divided into two parts: on admission, when included are: age, white blood cell count (WBC), glucose, lactate dehydrogenase (LDH), aspartate transaminase (AST), and after 48 hours there are evaluated hematocrit (Hct), calcium, blood urea nitrogen (BUN), base deficit, fluid loss, pO_2.

Glasgow scoring system uses pO_2, albumin, calcium, WBC, AST, LDH, glucose, and BUN. Hong Kong system requires just BUN and glucose (18). APACHE II is a scoring system used in intensive care unit based on multiparametric evaluation: temperature, heart rate, mean arterial pressure (MAP), respiratory rate, WBC, Hct, plasma Na+, plasma K+, creatinine, arterial pH, venous bicarbonate, pO2, alveolar–arterial pO2 difference, age, Glasgow Coma Scale (GCS), Chronic Health Score (CHS) (19).Other multifactorial prognostic scores are described, such as *Marshall* (based on MAP, FiO_2/pO_2, GCS, platelet count, creatinine), *BISAP –bedside index for severity in acute pancreatitis* (BUN, impaired mental status, SIRS, age, pleural effusion), *Panc 3* (Hct, body-mass index, pleural effusion), *JSS –Japanese severity score* (base excess, pO_2, BUN, creatinine, LDH, platelet count, calcium, CRP, SIRS, age), *HAPS –harmless acute pancreatitis score* (abdominal tenderness, Hct, creatinine), *POP –pancreatitis outcome score* (age, MAP, FiO_2/pO_2, arterial pH, calcium, BUN), *SOFA –sequential organ failure assessment* (MAP, FiO_2/pO_2, GCS, platelet count, creatinine, urinary output, bilirubin) (20, 21, 22, 23, 24).

The most widely used multiparametric scores are APACHE II score, Ranson and Glasgow criteria; APACHE II score initially developed for intensive care units requires a large number of variables being cumbersome in clinical practice, but can be used since admission; Ranson and Glasgow scores take 48 hours from admission, but require less amount of variables. Bedside index for severity in acute pancreatitis (BISAP) score is easier to use, requires those variables (vital signs, laboratories and imaging) commonly obtained in the emergency department, and can predict in-hospital mortality with higher accuracy (25).

Imaging prognostic scoring systems

These systems are based on computed tomography, a valuable method to depict pancreatic necrosis. Pancreatic necrosis is

more likely associated with severe clinical outcome and necrotizing pancreatitis and severe acute pancreatitis are practically interchangeable terms (26). Identifying pancreatic necrosis requires intravenous iodine-contrast administration and a delay in CT examination at 72 hours when necrosis is fully accomplished, to prevent underscoring.

Balthazar scoring system (27) developed in 1985 is based on the presence of pancreatic changes and the delay from onset of symptoms is 10 days. Balthazar scoring system uses a five-grade scale (from A to E) assessing the presence of pancreatic and peripancreatic inflammation, and fluid accumulation.

PSI –pancreas severity index (28) evaluates the pancreatic modifications with a delay of 72 hours; it is calculated by multiplying the largest anteroposterior diameter of the head by the largest anteroposterior diameter of the body. A PSI higher than 10 cm^2 is associated with severe acute pancreatitis.

CTSI –computed tomography severity index (1990) is based on Balthazar system, but adds necrosis of pancreatic parenchyma, requires intravenous contrast administration, and the delay is minimum 72 hours. CT severity index (CTSI) depends on the presence and degree of pancreatic and peripancreatic inflammation, and fluid accumulation in combination with the amount of pancreatic necrosis, using a 10-grade scale (29). It demonstrates a good correlation between necrosis, length of hospital stay, development of complication, and death, indicating no significant relationships between pancreatic necrosis and organ dysfunction, extrapancreatic parenchymal complications, and ultimate clinical outcome (30).

Modified CTSI (m-CTSI) (31) requires intravenous contrast administration, aggregates pancreatic inflammation, pancreatic necrosis and extrapancreatic complications (pleural effusion, ascites, thrombosis in portal venous system, arterial pseudoaneurysm, gastrointestinal tract involvement) on a 10-grade scale. m-CTSI shows a good correlation between calculated severity of pancreatitis and the outcome parameters, and with organ dysfunction.

Extrapancreatic inflammation on CT (EPIC) (32) score combines radiological manifestation of SIRS and organ dysfunction, without considering necrosis; incorporates pleural effusion, ascites, retroperitoneal and mesenteric inflammation.

Mesenteric edema and peritoneal fluid (MOP) score is based on the predictive value of intraabdominal inflammatory changes and severity of acute pancreatitis (33).

Simple prognostic score (SPS) combines biochemical and radiological parameters for risk stratification and prognosis of AP. SPS is based on quantifying serum lactate dehydrogenase (LDH > 900 IU/L), blood urea nitrogen (BUN >25 mg/dL), and the presence of pancreatic necrosis assessed by contrast-enhanced CT performed within 2 days after admission (34).

CONCLUSIONS

Concluding imaging prognostic scoring systems should be used for mortality prediction and for therapeutic guidance after the first 24-72 hours from admission, while nonspecific illness scoring systems (BISAP, APACHE II) are more suitable for the risk stratification within first 24 hours. Different prognostic scores should be applied to the different phases in acute pancreatitis, the goal being the correct identification of patients at risk to develop major complications or fatal outcome. Clinical scoring systems accurately correlate with

mortality and systemic complications, while imaging scoring systems diagnose clinically severe disease and have a better correlation with pancreatic infection and the need for intervention.

In our opinion we consider that on admission the selection of patients with mild AP should be based on the identification of pre-existing risk factors (obesity, advanced age), together with the common laboratory markers (BUN, creatinine) and chest-x-ray. Assessment of patients with a multifactorial scoring system (BISAP) at 24 hours after admission is important for identifying the group at risk for persistent organ failure. After 48-72 hours the group of patients at risk for organ failure should be checked by a prognostic score system plus CRP and a radiological score (CTSI, mCTSI). Monitoring in the late phase of AP must be based on CRP values, an organ failure score (Marshall) and repetition of contrast-enhanced CT should be used to diagnose the occurrence of complications and the changes in the extent of pancreatic necrosis or peripancreatic fluid collections.

NONSELECTIVE BETA-BLOCKERS IN PATIENTS WITH CIRRHOSIS: "THE THERAPEUTIC WINDOW" (Abstract): For over 30 years, nonselective beta-blockers (NSBB) have been successfully used for preventing variceal bleeding in patients with cirrhosis and portal hypertension. Nevertheless, recent studies suggest that NSBB may be effective only within a particular "therapeutic window" in patients with advanced liver disease. Outside of this window, in early stages of cirrhosis and in very advanced cirrhosis, NSBB may be ineffective and even potentially harmful. In this paper we review the beneficial effects and potential harms of beta-blocker therapy in cirrhosis and underline the most recent recommendations for their use in very advanced cases of liver disease. **Keywords:** LIVER CIRRHOSIS; BETA-BLOCKERS; THERAPEUTIC WINDOW.

Pathophysiological basis for using nonselective beta-blockers (NSBB) in patients with cirrhosis. The development of portal hypertension in cirrhosis is mainly due to:

a) An increase in resistance to portal blood flow, because of architectural modifications in the liver, and

b) An increase in portal territory blood flow, due to splanchnic arteriolar vasodilatation.

Therefore, NSBB goal in cirrhosis is to reduce portal pressure by two essential mechanisms:

a) *ß1- adrenergic blockade* , which decreases cardiac output, leading to reduced portal blood flow, and

b) *ß2- adrenergic blockade*, followed by an increase in arterial splanhnic resistance.

How did NSBB occur in the treatment of cirrhotic patient. The study of Lebrec et al. (3) published in 1981 in New England Journal of Medicine was the key-point in establishing the role of NSBB in the secondary prevention of variceal hemorrhage.

In 1987, the study of Pascal et al.(4) underlines the role of NSBB in the primary prophylaxis of variceal bleeding.

In 1991, Poynard et al.(5) meta-analysis together with other studies establishes that NSBB represent the first line therapy both in primary and in secondary prophylaxis of variceal hemorrhage.

The most important studies supporting NSBB usage in the treatment of cirrhotic patient are summarized by Phillip S. Ge., in

Journal of Hepatology from 2014 (1).

The indications of NSBB in cirrhosis

1. Primary prevention of variceal hemorrhage:

a) In cirrhotic patients with medium or large esophageal varices, NSBB lower the risk of first variceal bleeding (from 30% to 14%, compared to placebo) (6).

b) Primary prevention is not recommended in cirrhotic patients without esophageal varices, whatever the value of hepatic venous pressure gradient (HVPG).

2. Secondary prevention of variceal hemorrhage: NSBB reduce the rate of variceal rebleeding from 60% to approximately 40%.

3. Other benefits: NSBB might prevent the development of spontaneous bacterial peritonitis (SBP), by reducing intestinal permeability and bacterial translocation.

I. Pre-primary prophylaxis (to prevent the development of esophageal varices)

There are no data to confirm the benefit of using NSBB to prevent the development of esophageal varices, the most efficient method being the treatment of liver disease.

Studies showed that in patients without esophageal varices, NSBB (like *timolol*) have no role in preventing the development of esophageal varices, and the side effects are more frequent (7).

In conclusion, NSBB are not recommended in this set of patients.

II. Primary prevention (the prevention of first episode of variceal bleeding)

An important meta-analysis of 11 trials including almost 1200 patients evaluated the role of NSBB (*propranolol* or *nadolol)* in the primary prophylaxis of variceal haemorrhage (8) .

The results showed that in cirrhotic patients with medium or large esophageal varices NSBB lower the risk of first variceal bleeding (from 30% to 14%, compared to placebo) (6).

Other studies show that one bleeding episode is avoided for every ten patients treated with NSBB. In conclusion, NSBB reduce the rate of bleeding-related mortality compared to the control group (9).

Upon the size of esophageal varices, the recommendations are as follows:

According to Baveno VI Consensus, in cirrhotic patients with *medium* or *large* esophageal varices NSBB are recommended to prevent the first episode of variceal hemorrhage (6).

Still, the risk of bleeding depends not only upon the size of esophageal varices, but also upon the presence of the marks of bleeding (”red signs”) on the varices and on the severity of liver disease.

In patients with compensated liver disease (Child-Pugh A) and small esophageal varices without red signs, the risk of bleeding is 6%, while the patients with Child-Pugh C cirrhosis, with large esophageal varices with red signs have a risk of bleeding of 76% (10).

The set of cirrhotic patients with *small* esophageal varices are classified in two groups depending on the other factors which influence the risk of bleeding:

1. In patients with small esophageal varices and *low risk* of bleeding, which means without red signs and in the absence of severe liver disease (CHILD A), there are insufficient data that the use of NSBB would prevent the progression of esophageal varices. These patients may use NSBB to prevent the esophageal haemorrhage just in some individualized cases. The patients with small esophageal varices without therapy with NSBB must have endoscopy every 2 years, to evaluate the progression of

esophageal varices (11-13).

2. In cirrhotic patients with small esophageal varices and *high risk* of bleeding, meaning the presence of red signs and/or the presence of severe liver disease (CHILD-PUGH B or C), the treatment with NSBB is recommended (6,13).

III. Secondary prophylaxis of variceal bleeding

Secondary prevention means the prevention of rebleeding from esophageal varices, being addressed to those cirrhotic patients who have already had an episode of variceal haemorrhage.

Studies showed that patients who survive an episode of variceal haemorrhage have a high risk of rebleeding and death. In this set, untreated patients have a rebleeding rate of 60% at 1-2 years, with a mortality of 20-50% (14).

Besides, the prevention of rebleeding from esophageal varices was the first confirmed indication for using NSBB in the treatment of cirrhosis (the study of *Lebrec et al.* from 1981) (3).

It was demonstrated in trials that NSBB reduce the rebleeding rate from 60% to almost 40% (3,5,8).

According to the last guidelines, the combination of *NSBB* and *band ligation* is considered the maximal therapy for preventing rebleeding from esophageal varices. This provides the lowest rates of rebleeding, without major differences between the survival rates (compared to the patients treated only with NSBB). The early administration of NSBB may reduce the risk of bleeding till endoscopic band ligation. (6,15).

Other benefits of NSBB in cirrhosis include the prevention of other complications, like bleeding from portal gastropathy, the occurrence of ascites and of SBP (3,17).

The control of the efficiency of NSBB in cirrhosis targets:

a) *A hemodynamic response to NSBB* means a decrease in the HVPG below 12 mmHg or of 20% of the baseline value;

b) *The adrenergic response to NSBB* is defined as a decrease in the heart rate (measured 12-24 h after drug administration) of 25% of the baseline value;

c) *The dose of NSBB is decided* according to: a decrease in the heart rate (HR) of 25% of the basal value; the value of HR at rest not below 55/min; pay attention to the occurrence of side effects (3).

The side effects of NSBB

a) *Cardiac:* the exacerbation or precipitation of heart failure, symptomatic bradycardia, high grade heart block. The acute withdrawal of beta-blocker therapy can lead to accelerated angina, myocardial infarction and sudden death!

b) *Pulmonary:* increased airways resistance in patients with bronchospasm

c) *Circulatory:* the exacerbation of peripheral artery disease (claudication, absent pulses, cyanosis and gangrene)

d) *Metabolic:* in patients with diabetes mellitus, risk of severe insulin-induced hypoglycemia

e) *Other:* depression, fatigue and sexual dysfunction.

Contraindications to NSBB in cirrhotic patients

These may be classified as follows:

1) *General contraindications*

a) Absolute – severe heart failure, advanced heart block;

b) Relative – moderate chronic heart failure, asthma, chronic obstructive pulmonary disease, peripheral arterial disease, Raynaud syndrome, insulin-treated diabetes mellitus.

2) *Cirrhosis-related contraindications*
a) Portopulmonary hypertension;
b) Refractory ascites.

Is the therapy with NSBB in cirrhosis safe? How did this question occur? The same authors whose studies established the use of NSBB in the treatment of cirrhosis raised this problem!

In 2010, the study of Serste et al. (17,18) published in Hepatology concluded that NSBB should be contraindicated in cirrhotic patients with refractory ascites, leading to a shortening of survival.

Other authors, Wong and Salerno (19) showed that, regardless the design of the study, the safety of the treatment with propranolol in cirrhotic patients with refractory ascites is a problem.

In 2011, another trial of Lebrec et al. (3) postulated that NSBB are associated with the paracentesis-induced circulatory dysfunction (PICD), leading to a reduced survival rate in this group of patients.

"The therapeutic window" hypothesis. Recent studies of Krag et al. (20) suggest that the efficiency of NSBB manifests just during a window in the disease, named "*therapeutic window*" , in those patients with advanced cirrhosis.

Outside of this window, the therapy with NSBB may be ineffective in early stages of cirrhosis and potentially harmful in advanced cirrhosis (1).

Defining the term of "the therapeutic window". In early stages of cirrhosis, NSBB have no beneficial effect on survival and the adverse events may be more frequent (7).

These stages are defined by the following parameters: the esophageal varices are small or absent; intact cardiac reserve; sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS) have baseline activity; the risk of gut bacterial translocation is low, and the risk of mortality is also law (7).

In decompensated cirrhosis, NSBB improves the survival rate, lowering the rate of esophageal bleeding and of bacterial translocation.

This stage of cirrhosis has the following characteristics: medium or large esophageal varices; ascites; the cardiac reserve is intact, but declining; SNS and RAAS have increased but not maximal activity, and the risk of bacterial translocation and of mortality are increased (1).

The final (terminal) stages of cirrhosis are characterized by refractory ascites; impaired cardiac reserve, with baseline hypotension; SNS and RAAS are maximally stimulated and can no longer maintain adequate blood pressure (BP); high risk of gut bacterial translocation and of mortality (7).

In these stages, NSBB decrease the rate of survival as a result of the negative impact on cardiac reserve, lowering the perfusion of vital organs and precipitating the hepatorenal syndrome (HRS).

Why NSBB are not indicated in refractory ascites? The study of Serste et al. (18) from 2011 show that in cirrhotic patients with refractory ascites NSBB may cause a higher risk of paracentesis-induced circulatory dysfunction, thus reducing the rate of survival (2). NSBB (like *propranolol*) would prevent the adaptive hemodynamic response after large volume paracentesis, subsequently inducing PICD.

The factors which close the "therapeutic window" are:

a) The occurrence of refractory ascites and of SBP;

b) Systolic BP below 95 mmHg;

c) The presence of symptoms of orthostatic hypotension;

d) The occurrence of septic episodes;

e) Increased levels of serum creatinine.

The presented data show that the presence of medium or large esophageal varices opens the window of opportunity, which will be closed by the occurrence of refractory ascites, decreased medium BP and/or HRS. Taking into consideration the duration relatively limited of the ”therapeutic window”, some authors agree that NSBB should not be recommended in patients with low medical compliance and/or poor medical follow-up (21,22).

The initiation and continuation of NSBB therapy is ideal in those patients with home monitoring of BP and HR and who will have a close follow-up meaning frequent medical visits (23).

Concerning the ”therapeutic window” hypothesis, the results from studies and the existing evidences are still conflicting.

For example, the study of Galbois et al. (24) published in Hepatology contradicts some of the previous data, suggesting that NSBB are not associated with an inadequate hemodynamic response in patients with cirrhosis and severe sepsis.

For now, the recommendations of **Baveno VI Consensus (6)** are the following:

1) The safety of beta-blockers administration in cirrhotic patients with *refractory ascites* and/or *hepatorenal syndrome* was not demonstrated;

2) The patients with *refractory ascites* must be intensively monitored; if systemic hypotension or azotemia occur, we must reduce the dosage of NSBB or even discontinue the BB therapy;

3) If NSBB therapy is discontinued, the patient will need esophageal band ligation for preventing variceal bleeding;

4) Until practical data from randomised trials arrive, NSBB must be discontinued or the dose must be reduced in patients with refractory ascites if: systolic BP is below 90 mmHg; serum creatinine is raising and/or hyponatremia below 130 mmol/l occurs;

5) The consequence of discontinuing the BB therapy on the prevention of esophageal bleeding is not known;

6) If variceal bleeding or SBP occur after discontinuing the BB therapy, we may restart the treatment if the above parameters became normal.

CONCLUSIONS

In conclusion, the therapy with NSBB requires special attention in two clinical settings:

a) Decompensated cirrhosis in terminal stage, and

b) Refractory ascites.

It remains unclear if, after closing the ”therapeutic window” of NSBB in cirrhosis, this would be a definitive closure or not, referring to the possibility of restarting the beta-blocker medication after a period of time.

THE PERSONAL REPRESENTATIVE-THE "ACHILLES HEEL" OF THE ROMANIAN MENTAL HEALTH LAW SYSTEM (Abstract): The psychiatric law system was created with the sole purpose of protecting patients with mental illnesses, a vulnerable segment of the population. The laws regarding voluntary and non-voluntary admission of mental patients have been reformed in many European countries. After 1989, Romania starts to gradually benefit from a law system that meets the requirements of modern society. From this general context the Mental Health Law takes form, with the main purpose of ratifying the relationship between patient and psychiatrist. This system provides a new, more modern approach but also proves to have certain flaws. One of the most obvious is the aspect regarding the personal representative, which generates both ethical and professional conduit problems, difficult to manage from the standpoint of modern medicine. Minimizing the effects of such an error is possible by simply considering the small number of solutions suggested by the author in the end of this article. **Keywords**: MENTAL HEALTH LAW, PERSONAL REPREZENTATIVE, PSYCHIATRIC.

Mental health (MH) is an important issue not only in Romania, but also worldwide. In psychiatry, like in many other medical fields, ethical problems are a common fact, both in research and in clinical practice. Regarding psychiatric assistance, there are two ways of providing it: voluntary admission and treatment, at the patient's request or non-voluntary admission. In psychiatric institutions, non-voluntary admission for patients with MH problems is allowed only after all other means of voluntary admission have been properly taken into consideration. Non voluntary admission is one of the most complex problems in psychiatry (1).

The high complexity of cases addressed by psychiatry, the increased number of causes and effects treated, represent a fertile ground for both ethical and deontological problems. Many of these issues exist due to the high subjectivity present regarding important aspects like socio-economic status, psychological status and biological

variables. Regarding the results of issues, Constatin B. (2) states that, from the total number of complaints, coming from patients, about abusive non-voluntary admission, approximately 90-95% are unjustified. According to World Health Organization, 78% of countries worldwide, which represent about 69.1 % of the entire population of the planet, have a law system which deals with mental health (1). WHO reports show that 57.1% of the Middle Eastern countries have laws which deal with these issues, while the percentage for European countries is 91.8%. Over 50% of MH laws in effect today date as early as 1990, 25% having been introduced after 2000. Approximately 16% of laws are older than 1960. Although a legal system dedicated to MH exists, that doesn't automatically mean that human right are always respected. As a result in countries with an obsolete law system, breaking human rights is often more common that respecting them. Currently, guiding all actions according to the human rights agenda is an ethical obligation especially in countries part of international agreements. The European Court for Human Rights, supported by the European Union court, is a strong advocate for patients with MH problems, especially in member countries (1, 2).

In many cases, the parties involved are individuals whose knowledge about these ailments varies from high to none. This is why, frequently, it is hard to cover all aspects and issues of MH pathology, because it is encountered in small part of the population.

Regarding minorities, Buda O (3) says that "they can be considered individuals which are disadvantaged, almost continually or even traditionally, according to rules of certain communities or to popular views, by dominant individuals, through discrimination, scrutiny, punishment". Stigma also contributes substantially to the diversification and amplification of possible errors in a discipline where ethical limits are difficult to establish. Between those involved in MH care and stigma, a complex relationship exists: they can be a discriminating agent, they can fight against it or they became themselves a target (4, 5). Stigma in a society can be reduced either through education, protest and a new law system, through self-management of stigmatization or through social support (4, 6). Social stigma and labeling is a violation of freedom and human rights (7). The subject of nondiscrimination in Romania, a European Union member (8, 9), is a great challenge and amongst those who provide psychiatric care, stigma is an important issue.

THE PSYCHIATRIC PATIENT'S PERSONAL REPRESENTATIVE

In Ireland (10, 11), non-voluntary admission in psychiatric institutions is requested by husband / wife or another close relative, a law representative or member of the police. The admission has a validity period of 21 days, after which, if it is renewed, the admission can last as long as 3 months, or a maximum of 6 months. Periods can be extended, but they should not exceed 1 year. A patient's non-voluntary admission or its extension is automatically managed by a MH committee. The committee provides each mentally ill patient with a legal representative for free legal support. Currently, the main focus of the Irish Parliament is the Mental Capacity and Legal Representative Irish Act. A new legislation with new stipulations regarding non-voluntary admission is considered necessary in Ireland, to protect the rights of pa-

tients with MD. According to studies, one year after their discharge, 60% of patients admitted through non-voluntary means, felt that their coercive admission was justified. Although MHA 2001 in Ireland benefits from new stipulations regarding mentally ill patients, the advance directive represents an issue that needs to be considered further.

The economical aspect is an issue that has not been discussed and investigated thoroughly in studies involving individuals with MD. Specialty literature has paid little attention to this subject also. Financial issues are very common, especially amongst patients with severe MD, such as schizophrenia patients. Thus, establishing a financial representative would be very useful for some patients with serious psychiatric disorders (12). The medical team may adopt a paternalistic attitude if the patient is considered unable to make decisions on his own. From a legal standpoint, a patient can be considered unfit to make a medical decision and, thus, a third party is required (usually a family member). A paternalistic attitude of the medical team is not always justified; therefore, some studies support the involvement of a third party (lawyer, relative) in psychiatrist-patient relationship (13). When the patient is considered incapable, a legal or personal representative may give his consent for both healthcare and research. Clinical research can include subjects with MD which are not able to make a decision, and, in these cases, the legal or personal representative can decide for them. The mental capacity of patients with MD is a subject that involves many ethical and legal discussions, especially in situations that require coercive measures (14, 15). The patient should be represented by a legal representative, who can be appointed if the patient can not represent themselves. If the patient lacks judgment, consent will be given by the patient's legal representative.

Individuals incapable of self-autonomy, relative or absolute, are considered vulnerable persons. There are two vulnerable population groups: the first group includes some patients with MD, children, coma patients, individuals who lack self-autonomy. This group lacks the ability to decide for themselves, and need a permanent representative to protect their interests. The second group incorporates individuals who can be manipulated, coerced to participate in human research studies. This vulnerable group is characterized by an impaired reasoning ability and not a lack of judgment. This group can also include patients found in extreme suffering or poverty, etc. (16, 17).

In Romania, there have been numerous efforts to decrease the degree of subjectivity specific to psychiatry, often found in relationships with other medical specialties, institutions or forums. This issue is covered by the Mental Health Law, the law 487 of 11 July 2002 (129/2012), developed by the Romanian Parliament (18, 19).

LAW 487/2002 VS. LAW 129/2012

The subject of this article covers some aspects coming from the imprecise definition of certain terms used by the aforementioned Law, which can bring forward interpretations that may cause dysfunction and / or abuse for all parties involved. Article 5 of Law 487/2002 (law 129/2012) defines patients with MD. Thus, an individual with MD is "a mentally ill person, a person with mental imbalance or mentally underdeveloped or alcohol and drugs addiction and the person who exhibits other disorders that can be classified, in accordance with cur-

rent diagnostics used in the psychiatric medical practice." The law specifies degrees of MD, also referring to a person with serious MD, characterized by the fact that "he is not able to understand the meaning and consequences of his behavior, thus requiring immediate psychiatric help". An important aspect is that, of all mental pathology, between 20% and 30% of cases can be considered patients with severe MD. Given their complexity, these cases are assisted by a therapeutic team, which is defined by law as "all MH professionals involved in providing mental health care, medical assistance and the caring of a person with MD, such as: physician, psychiatrist, psychologist, nurse specialist, social worker, occupational therapist and paramedical personnel". Regarding people with MD, the Law promotes the concept of mental capacity, meaning the "attribute of the mental state to be compatible, at a time given, with the exercise of civil rights or specific activities." It is obvious that it mainly addresses the legal aspects of mental capacity and focuses less on the medical ones, not covered by the definition. Based on this type of definition, only two categories exist, scarcely seen: the first one compatible with the exercise of human civil rights and other specific actions, and the second one incompatible. Almost all patients with severe MH problems belong to the second.

Law 487/2002 republished, makes a number of clarifications regarding consent, starting from its definition: "the agreement of a person regarding admission procedures, diagnosis and treatment, which must be free from any coercion and preceded by understandable and full access to information, showing the advantages, disadvantages and alternatives procedures, which can be further confirmed whenever needed or at the initiative of the person concerned ". In conclusion, valid consent can legally be obtained from individuals whose psychological distress is placed in the first category and not in the second.

The law states that the patient or his legal representative has the right to retract given consent and, in this case, the psychiatrist is obligated to inform the patient or his legal representative regarding the consequences of discontinuing treatment. But, if the specialist decides that calling off treatment could pose a danger to both patient and the individuals around him, because of his impairment, he has the right to continue with appropriate medical therapy for as long as strictly required, with the condition of notifying and presenting the case to a specialized procedural committee. If we consider informed consent an action, some patients will be capable to understand both content and consequences while others won't. Judgment, legally speaking, represents "that aspect of mental capacity which deals with a specific event and the individual's capacity to understand its significance and results".

Even now, in Romania, the law defines two categories of legal representatives for a patient, but does not take in consideration the mental capacity of that said individual: the legal representative ("appointed person, by law, to represent the interests of a mentally ill person) and the personal representative ("a person, other than the legal representative, who accepts to represent the interests of a mentally ill patient, chosen by the person in question"). While the legal aspects of the legal representative are amply and clearly covered, the legal framework regarding the attributions and the appointment of the personal representative

are loose, thus allowing a number of interpretations adverse to psychiatric practice. One of the most important issues, not covered by context, is the fact that a personal representative should have a mental capacity compatible with exercising civil rights or specific actions. This flaw often leads to situations in which a patient with severe mental issues exercises his right to appoint a personal representative and chooses an individual who also suffers from severe mental problems. He is given by law, as we will see a lot of decision-making power. A second shortcoming is the fact that the moment of appointment of the personal representative is overlooked (before, at or during hospitalization) or the period of time he is allowed the exercise the power with which he was invested. A third issue is created by the absence of information concerning the existence of a legal document that mentions the personal representative named by the patient, which can be used in relation with the institutions that assist them. The absence of such a document favors an opportunistic attitude coming from the patient, who can– depending on the situation - occasionally appoint more than one personal representative to serve his interests. Patients are informed about this right upon admission, when they are made aware that the content of the informed consent template, including the Mental Health Act, as an annex. For non-voluntary admission cases, the law provides extended information, offering a wide and varied range of possibilities to apply for admission, even if the solicitor it not the patient's legal or a personal representative. According to law 487/2002, republished (Law 129/2012), non-voluntary admission is "against the will of the patient or without his consent". Not being able to realize the severity of his disease, the patient often considers admission useless or even an abuse. Hence the interpretation, easy to deduce, that those who requested admission do not represent the interests of the patient, the later one refusing their representation and soliciting another representative (which he considers more "reasonable").

Regarding the evaluation of MH state and the procedures needed to diagnose mental illnesses, in chapter 3 the law brings forward again the two types of patient representatives. So, according to article 10, law 487/2002 republished, "a patient's mental state can only be evaluated directly by a trained specialist". It is also stated that "MH evaluation can be performed after the subject has been properly informed and after he has given his consent, with the exception of specific situations, established by law, when an individual presents difficulties understanding direct consequences of such a decision, situations when a legal or personal representative is required" according to article 11, law 487/2002 republished (law 129/2012). According to article 15 law 487/ 2002 (law 129/2012), the results of MH evaluation must be recorded in official medical files and also made available to the patient, his legal representatives or at the express request of proper authorities. Also, the treatment plan a psychiatrist is obligated to establish whenever a mental illness is diagnosed, must be presented to both patient and legal representative. Furthermore, "to establish and apply a treatment plan, the psychiatrist is obligated to have proper consent and to respect the patient's rights to assistance when it comes to making such a decision".

However, the law refers to situations in which the psychiatrist can establish treat-

ment without the patient's consent: the patient's behavior is an immediate danger to himself or those around him; the patient lacks mental capacity to understand his disease and the need of medical treatment; the patient has a legal guardian established by law or court ordered; the patient is underage thus the psychiatrist is required to ask and obtain consent from his legal or personal representative.

When the psychiatrist cannot obtain the patient's consent (20) or consent from his legal or personal representative, he can act "on his own responsibility, establishing a diagnosis and a treatment plan he deems necessary, for a period of time strictly necessary to achieve the aim pursued" according to MH law. However, the law requires that such cases must be brought to the attention and scrutiny of a specialized procedure committee. Whenever a patient and his legal or personal representative are in a conflict of interests, the psychiatrist has the right to ask proper authorities for a new legal representative. This legal aspect, gives the psychiatrist the opportunity to correct a possible wrong decision made by the patient when he chose a personal representative, but is a procedure that consumes a lot of time and resources. Furthermore, such a procedure lacks a proper protocol in accordance with the situation, established by law, thus making it more difficult to apply.

According to articles 34 law 487/2002 republished (law 129/2012), "any mentally ill patient or former patient or his legal/personal representative can submit a complaint whenever a patient's rights are violated". This article gives a patient's legal representative the possibility to delay any treatment plan. To resolve such an issue a certain amount of time is required, during which the patient is not subjected to any treatment or procedures, established by law, for serious medical conditions or relapses. In section 3, "The rights of mentally ill patients", the law gives the legal representative a list of actions he can choose from, interventions that can trigger lengthy and complex legal procedures, which may impair the quality and speed of psychiatric treatment. According to article 44 MH laws republished, "from the moment he is admitted in a mental healthcare institution, every patient must be informed, as soon as possible, clearly and understandably, about his rights, what they mean and how he can act according to them, in accord to legal provisions. If the patient is unable to understand this information and he will incapable to understand them in the near future, his right will be brought to the attention of his legal or personal representative". According to article 62 law 129/2012 "the patient or his legal/personal representative can apply for a forensic psychiatric examination or any other procedure, according to law".

CONCLUSIONS

Aspects illustrated previously around legal stipulations, when the patient and his legal/personal representative represent a dysfunctional element in psychiatric practice, can be corrected by establishing a more precise legal role for the legal representative.

As a whole, this article illustrates one of the main issues of Mental Health Law, tailored to current international legal models. The issues discussed in the article are some that obligates the psychiatrist and the therapy team to ethical and professional approaches that have more of a Hippocrates 'oath base than a legal base, which would

be beneficial for all parties involved.

Based on these considerations and continued comparative analysis of the laws of different countries, we consider the following issues as requiring modifications, additions or revisions in Romanian law: implementing an advance directives legal system in which the patient may express wishes for the future of his psychiatric care, including aspects regarding the personal representative.

NEWS

TWO SPATIOTEMPORAL PATTERNS OF ^{123}I-IOFLUPANE SCINTIGRAPHIC UPTAKE IN PARKINSON'S DISEASE

To assess correlations between the degree of dopaminergic depletion measured using single-photon emission computed tomography (SPECT) and different clinical parameters of disease progression in Parkinson's disease (PD) was conducted a retrospective study including 411 patients (60-80 years,of age) undergoing (123)I-ioflupane SPECT scans between 2003 and 2013. According to their clinical diagnosis, there were 301 patients with PD (163 men) and 110 patients with nondegenerative conditions included as controls (55 men). Comprehensive and operator-independent data analysis included spatial normalization into standard space, estimation of the mean uptake values in the striatum (caudate nucleus + putamen) and voxel-wise correlation between SPECT signal intensity and disease stage as well as disease duration in order to investigate the spatiotemporal pattern of the dopaminergic nigrostriatal degeneration. Increasing disease stage was associated with an exponential decrease in (123)I-ioflupane uptake ($R(2) = 0.1501$) particularly in the head of the ipsilateral caudate nucleus ($p < 0.0001$), whereas increasing disease duration was associated with a linear decrease in (123)I-ioflupane uptake ($p < 0.0001$; $R(2) = 0.1532$) particularly in the contralateral anterior putamen ($p < 0.0001$). These two distinct spatiotemporal patterns of posterior to anterior dopaminergic depletion associated with disease stage and disease duration in patients with PD can be used for clinical and research applications. (Badoud S et al. Distinct spatiotemporal patterns for disease duration and stage in Parkinson's disease. *Eur J of Nucl Med and Molec Img* 29.08.2015 Doi:10.1007/s00259-015-3176-5, 1-8)

INTERVENTIONAL CARDIOLOGY AND ELDERLY PATIENTS: WHEN IS IT TOO LATE? (Abstract): **Aim:** To analyze the incidence of complications associated with interventional cardiology (myocardial revascularization techniques or permanent cardiac pacing) in hospitalized elderly patients. **Material and methods:** Retrospective study of 40 patients aged ≥ 65 years, with a history of interventional cardiology: percutaneous coronary intervention (PCI), coronary artery bypass graft (CABG) or permanent cardiac pacing who were admitted to the Geriatric Clinic in the interval January-December 2014. The main causes of current readmission were investigated. Comprehensive geriatric assessment (CGA), including nutritional, functional and psychological assessments, were performed. **Results:** Most cardiovascular procedures were performed in patients aged ≥ 70 years. Current hospital admission was mainly the result of non-adherence to medical treatment. None of the patients were admitted due to complications of any of the above mentioned procedures. CGA performed in these patients revealed: increased autonomy at home reduced cognitive impairment, decreased rate of mild depression and risk of undernutrition. Psychological examination confirmed that quality of life improved in all patients after interventional cardiology. **Conclusions:** Interventional cardiology confers major benefits in elderly patients, with low rates of late complications, and influences prognosis and quality of life. **Keywords:** INTERVENTIONAL CARDIOLOGY, ELDERLY, QUALITY OF LIFE.

One of the major cardiovascular risk factors is ageing itself, mainly due to inexorably advancing atherosclerosis but also to the inevitable ageing of the cardiovascular system and long period of time for other risk factors to negatively influence the cardiovascular condition (1). Moreover, elderly patients frequently develop cognitive and functional impairments (sleep disorders, chronic pain etc.), which would require complex drug administration and special care in establishing a therapeutic plan. Given the high prevalence of cardiovascular diseases among the elderly, special attention for this group of patients is granted in the latest ischemic heart disease guidelines but information provided derive mostly from carefully selected randomized trials with

carefully selected elderly groups. Patients aged ≥ 80 years are almost completely absent in trials, and when included, it would be only those without co morbidities, which are the hallmark of their age. We face an interesting paradox: the patients at the highest cardiovascular risk should benefit most from the treatment recommended by the guidelines, but this category is not really part of data supporting the guidelines (2).

The recommendations for interventional cardiology in the elderly population have permanently been updated in the past decade. The 2012 and 2013 guidelines regarding the management of stable angina and acute coronary syndromes emphasize that older patients are more likely to have diffuse and severe coronary atherosclerosis with a higher prevalence of three-vessel and left main coronary artery disease. The guidelines acknowledge the less frequent use of evidence-based therapies in older adults, due to therapeutic challenges secondary to age-related changes: altered pharmacokinetics (due to reduced muscle mass, renal and/or hepatic dysfunction, and reduced volume of distribution) and pharmacodynamics (increased risks of hypotension and bleeding) (2), and the risk of polypharmacy and iatrogenesis. Therefore, there is a certain degree of reluctance in the application of guideline recommendations in older patients, often based on a subjective risk evaluation.

This article aims to explore the benefits and limitations of interventional cardiology in the geriatric population.

MATERIAL AND METHODS

We retrospectively analyzed a group of 1219 patients aged ≥ 65 years old who were admitted to the Geriatric Clinic of the Iasi "Dr. C.I. Parhon" Hospital, Romania in the interval January-December 2014. Of the total number of patients, 40 patients (3%) had undergone at least one of the following procedures: percutaneous coronary intervention (PCI), permanent cardiac pacing, and coronary artery by-pass graft (CABG). Of them, 4 patients (10%) underwent surgery for hip fracture and were admitted for postoperative assessment and 2 patients (5%) were recovering from oncological surgery.

Patients were divided into two groups in order to assess the significant gender differences. The parameters of interest were: baseline demographics (age, gender, and social origin), causes of current admission (medication non-adherence included), symptoms and signs (angina equivalents included), complications of cardiovascular procedures, course, and discharge status.

Every patient had been subjected to a comprehensive geriatric assessment (CGA) and a psychological examination, which included: ADL (Activities of Daily Living) (3), IADL (Instrumental Activities of Daily Living) (4), MMSE (Mini Mental State examination) (5), GDS (Geriatric Depression Scale) (6) and MNA (Mini Nutritional Assessment) (7).

Data were collected from the patient medical records by the medical staff involved in this study. The collected data were analyzed by SPSS 18.0 software, using the Paired T Test for quantitative analyses and Chi-square Test for differences in proportions. The possible influence of every parameter in each of the two groups (male vs female patients) was evaluated. When the study of correlations indicated a degree of influence, we analyzed if there was a statistically significant relationship between that parameter and its dependent variables. The statistical significance was defined in a 95% confidence interval ($p<0.05$). For the geriatric assess-

ment we carried out an overall descriptive group analysis.

RESULTS

The analysis of the demographic parameters showed that the mean age was 77.5 years (range 65 - 90 years). The cohort included mainly old (52.5%) and young-old (35%) patients, with no significant difference between genders (p=0.993). As to the area of residence, 55% of patients lived in urban areas and 45% in rural areas, with no significant difference between genders (p=0.923).

In conclusion, the study group was homogenous in terms of gender, age group and area of residence (tab. I).

The main cardiac procedures were permanent cardiac pacing (42.5%) and coronary angioplasty (40%). The mean age at the time of intervention was 71.6 years. CABG was more frequently performed in males, and in this group there was a threefold increased relative risk of readmission.

TABLE I

Analysis of the demographic parameters

Parameters	All cohort (n=40)	Male (n=23)	Female (n=17)	p
Age (years) mean±SD *limits	77.5 *(65-90)	77.21±6.45	76.41±4.74	0.300
Classification				
Young-old (65-74 y)	14 (35.0%)	8 (34.8%)	6 (35.3%)	0.993
Old (75-84 y)	21 (52.5%)	12 (52.2%)	9 (52.9%)	
Oldest old (85+ years)	5 (12.5%)	3 (13.0%)	2 (11.8%)	
Area of residence				
Rural	14 (45.0%)	10 (43.5%)	8 (47.1%)	0.923
Urban	21 (55.0%)	13 (56.5%)	9 (52.9%)	

The symptoms at admission were various, but most patients presented with dyspnea of cardiac origin (72.5%), mainly due to discontinuation of treatment (47.5% of the patients). None of the symptoms were due to complications following cardiac procedures (e.g. stent/graft occlusion, pacemaker dysfunction) (tab II).

The geriatric assessment showed that most patients had increased autonomy at home. ADL test showed that 31 patients (77.5%) had full function, 9 patients (22.5%) had moderate impairment, and no patient had severe impairment. The IADL test showed that all patients were independent; none of them needed any assistance at home. CGA and psychological examination concluded that 34 patients (85%) had normal cognitive function and only 6 patients (15%) had mild cognitive impairment. There were no signs of depression in 14 patients (35%), while mild depression was detected in 17 patients (42.5%) and severe depression in 9 patients (22.5%). The MNA scale showed that most of our patients were at risk for malnutrition (26 patients, 65%), 8 patients suffered from malnutrition (15%), while only 8 patients (15%) had a good nutritional status.

Patients who underwent surgery for hip fracture had a good postoperative outcome and their recovery period was within normal limits, since rehabilitation was initiated after the same period of time as in patients without cardiac surgery.

TABLE II

Clinical history and medical status

*** increased relative risk in the female population**

Parameters	All cohort (n=40)	Male (n=23)	Female (n=17)	p	RR (IC95%)

DISCUSSION

Interventional cardiology is often controversial, and strong debates argue the optimal therapeutic indications in patients ≥ 75 years old who require myocardial revascularization and/or cardiac pacing treatment.

Several studies suggest an increased mortality rate in older patients compared with young adults undergoing a myocardial revascularization procedure (interventional or surgical) (8), but the data on this issue are often contradictory.

The CRUSADE Initiative points out that 7% of patients presenting with STEMI were not considered for myocardial revascularization because of their advanced age (9). If coming to choose between techniques, a larger number of geriatric patients

seem to benefit from PCI compared to CABG, but their age should not be the sole criterion for the type of revascularization. Their selection should be based on the assessment of frailty, co morbidities, life expectancy and personal desire (2, 10, 11).

Evidence from the medical literature shows that PCI should be a viable treatment option in elderly patients (12-15). PCI is a low-invasive procedure and carries a small likelihood for cognitive impairment. In carefully selected patients with clinically relevant coronary stenosis, PCI may provide greater symptomatic relief than medical therapy. Patients presenting with ST elevation myocardial infarction (STEMI) who are expected to live an autonomous life style after discharge are the best candidates for PCI in order to secure vessel patency and achieve myocardial salvage. Still, PCI is frequently avoided in elderly patients because age is a potent and independent negative predictor of death, myocardial re-infarction, stent thrombosis, and re-hospitalization (11). Hence, a careful follow-up of these patients, associated with maximizing their medical treatment and therapeutic education to prevent non-adherence are mandatory.

The determination of geriatricians to assess the benefit of interventional cardiology in the elderly patients is reflected by studies that included specific subgroups, such as octogenarians (10) and nonagenarians (11, 12). Liu et al. (16) compared 112 octogenarians and 336 young adults who underwent PCI between 1993 and 2010 and found no significant differences with regard to procedural success, in-hospital complications and major cardiovascular events 1 year after the procedure. The authors concluded that PCI remains a reliable treatment for carefully selected elderly patients, and complying with the above mentioned recommendations, such as having a good radial or ulnar access site, limiting contrast load and optimizing fluid status to prevent contrast associated nephropathy, and favoring bare-metal stents. However, other studies (17) showed that PCI was associated with lower mortality and morbidity on short-term, while CABG was followed by superior outcomes on the long-term. The same conclusions are found in other studies that included octogenarians: CABG poses a greater risk of short-term complications compared with PCI, but provides a better survival (18, 19).

Maintaining quality of life up to patient expectations should be an important parameter to take into account when managing geriatric patients (20), and, therefore, many studies analyzed if patient status after PCI correlated with a better quality of life. Thus, quality of life of octogenarians following PCI appears to be acceptable, with main improvements in their cognitive status (8). Spertus et al. (21) found that the only factors independently associated with a better quality of life 1 year after PCI were improvement of physical function and decrement of angina frequency.

Frailty, co morbidity and quality of life are highly prevalent in elderly patients undergoing PCI. These factors should be incorporated in current risk-prediction models along with traditional cardiovascular risk factors in order to assess the risk of patients undergoing PCI. For example, their inclusion improved the discriminatory ability of the Mayo Clinic risk score to evaluate the long-term prognosis of elderly patients after PCI (22). Long-term mortality/myocardial infarction were significantly higher in patients considered to be frail.

Hip fracture is highly common among

geriatric patients. For the management of these patients, Papp (23) developed a useful algorithm to assist the surgeon in gathering important information and developing perioperative approaches to treatment according to the personal medical profile of the patient.

While the incidence of acute myocardial infarction in younger adults is increasing, the conditions that require a pacemaker implantation (complete atrioventricular block, atrial fibrillation with a spontaneous heart rate < 40 bpm, sick sinus disease, etc.) are prevalent in older patients. Some statistics estimate that 70-80% of pacemaker implantations are performed in patients aged ≥ 65 years (24).

The most common complications associated with a pacemaker implantation are: pocket hematoma, infection of the pocket, pneumothorax – at the time of implantation, and late complications: lead displacement/failure, lead endocarditis, pocket fibrosis and myocardial rupture. Ozcan et al. (25) published in 2013 a prospective study in which they compared the incidence of these complications in older patients with younger patients. Their results showed that pacemaker implantation in elderly patients is a safe procedure when performed by an experienced team, and patients over 70 years old may even have fewer complications than younger patients. The explanation could be the higher proportion of dual chamber pacemaker implantation in younger patients, which is frequently associated with atrial lead dislodgement. None of the patients included in our study presented with late complications of pacemaker implantation.

CONCLUSIONS

Our study, even though a single-center study on a small number of patients for the prevalence of complications related to past cardiac interventions, confirmed that interventional cardiac surgery is beneficial in elderly patients. The study group was homogenous in terms of gender, age group and area of residence, but the absence of statistically significant differences between the analyzed parameters should be taken with caution.

Late complications of PCI, CABG or pacemaker implantation were not recorded in our study. Although most procedures were performed in patients over 70 years of age, the cognitive, psychological and social status of our patients had a positive impact on the outcome of these procedures. Hence, according to current evidence, the decision to perform an invasive cardiac procedure should not be based on chronological age alone, but rather on each patient's general eligibility and the clinical circumstances as a whole.

MYTHS AND CONTROVERSIES IN HYPOGONADISM TREATMENT OF AGING MALES (Abstract)**:** Low T is an independent risk factor for metabolic syndrome (MetS) and type 2 diabetes mellitus (T2DM) development; patients with these clinical conditions should be screened for hypogonadism. Testosterone replacement therapy (TRT) ameliorate**s** libido, improves bone mass, improves insulin resistance, reduces fat mass and increases lean body mass with no change in body weight. There are no evidences that testosterone therapy increases the risk of prostate cancer but it is certain that testosterone stimulates growth of metastatic prostate cancer. TRT has an antiarrhythmic and a vasodilator effect, independent of the nitric oxide effect. Patients with heart failure have low levels of testosterone**,** and TRT improves exercise capacity. Men with low testosterone have risk for premature death. Cardiovascular adverse effects of testosterone therapy are under discussion. We need large prospective placebo-controlled randomized trials to determine definitively the cardiovascular risks of TRT. **Keywords**: MALE HYPOGONADISM, TESTOSTERONE REPLACEMENT THERAPY, DIABETES MELLITUS, METHABOLIC SYNDROME, CARDIOVASCULAR RISK, MORTALITY.

Late onset hypogonadism (LOH) is a clinical and biochemical syndrome associated with advancing age and characterized by symptoms and a deficiency in serum testosterone level; it may cause a significant deterioration in quality of life and functional alterations of multiple organs (1,2). In the Massachusetts Male Aging Study (MMAS) after the age of 40 the average age-related reduction in total testosterone is 0.8% per year, whereas free testosterone declines by 1.7-2.8% per year; the prevalence of syptomatic hypogonadism is between 6-12% (3). In European Male Aging Study (EMAS) the prevalence of hypogonadism is 2.1% and increase with age from 0.1% for men 40-49 years of age to 5.1% for those 70-79 years (4). The odds of having low testosterone levels is 2.4 higher for obese men, 2.1 times higher for men with diabetes, 1.58 times higher for men with hypertension, and 1.5 times higher for those with dyslipidemia or chronic obstructive pulmonary disease (1,5).

Clinically, the syndrome is characterized by:

- reduce sexual desire, low libido, erectile dysfunction, reduction of spontaneous erections

- breast tenderness, gynecomastia
- corporeal hairiness reduction, reducing the frequency of shaving
- mood changes with reduced intellectual activity, cognitive functions, spatial
- orientation ability and memory
- fatigue, depression and irritability, depressed mood
- sleep disorders, hot flushes , sweating
- decrease muscle mass and muscle strength
- increased body fat mass, increased BMI
- osteopenia / osteoporosis and increased risk of fracture
- mild anemia (Hb and Ht normal values for women) (6, 7).

The MMAS has shown that a lot of co morbid conditions are strongly associated with declining testosterone levels; in these cases it is suggested measurement of testosterone level:

- metabolic syndrome
- obesity
- hyperlipidemia
- hypertension
- elevated fasting glucose and serum insulin elevated C reactive-protein
- diabetes mellitus type 2
- chronic obstructive pulmonary disease
- cardiovascular disease (including aortic atherosclerosis)
- inflammatory arthritic disease
- HIV-associated weight loss
- end stage chronic kidney disease
- low trauma fracture
- sellar mass, radiation in the sellar region
- chronic use of glucocorticoids and opioids
- hemochromatosis (2, 8, 9).

The diagnosis is made by subnormal values of total testosterone and the combination of characteristic symptoms.

Testosterone circulates bounded to Sex Hormone Binding Globulin (SeHBG) (68%), loosely bound to albumin (30%) and only 0.5-3% is free. Total testosterone levels may vary depending on the SeHBG value.

Total Testosterone is determined in the morning, 8-11 AM, by RIA, immunometric methods or ideal liquid chromatography tandem mass spectrometry (LC-MS), 2 determinations at intervals of at least 1 month (10). The dosage of **free testosterone** is expensive; the only method validated is by equilibrium dialysis. **Bioavailable Testosterone** (free plus the loosely bound to albumin) is determined by ammonium sulphate precipitation method, or is calculated from total testosterone, SeHBG and albumine level.

SeHBG - binds testosterone with higher affinity than estrogen. The values are increased in elderly, liver cirrhosis, hyperthyroidism, anticonvulsant therapy, estrogen, HIV and decreased in moderate obesity, hypothyroidism, nephrotic syndrome, acromegaly, corticosteroid use, androgen treatment, progesterone (10, 11).

It is not recommended a population screening for androgen deficiency (2); in certain circumstances (see above), there is a high prevalence of low testosterone levels and it is suggested measurement of serum testosterone (tab. I).

Testosterone treatment is recommended:

- at patients with typical clinical signs of androgen deficiency and biological confirmation
- for a limited time for patients with HIV infection, low testosterone and weight loss to increase and maintain lean mass (3-6 months)
- short chronic glucocorticoid therapy (prednisone equivalent 5-7.5mg/day) due to inhibition of gonadotropic axis (2,12).

TABLE I

Biochemical definitions of hypogonadism

Society	Serum testosterone values		
EAA, ISA, ISSAM	<3.4 ng/ml	<340 ng/dl	<12 nmol/l (mild)
EAU, ASA, ISSM	<2.31 ng/ml	<231 ng/dl	<8 nmol/l (severe)
ES	<3.0 ng/ml	<300 ng/dl	<10.4 nmol/l
AACE	<2.0 ng/ml	<200 ng/dl	7 nmol/l

EAA = European Academy of Andrology, ISA = International Society of Andrology, ISSAM = International Society for the Study of Aging Male, EAU = European Association of Urology, ASA = American Association of Urology, ISSM = International Society for Sexual Medicine, ES – Endocrine Society, AACE = American Association of Clinical Endocrinologists

The goal of treatment (2, 11) is to safely restore testosterone to normal physiological levels, thereby ameliorating symptoms associated with TD and improving patient health and well being.

Options for testosterone therapy include oral preparations (2-3 doses per day), buccal agents, injections (at 2-3 weeks or at 12-14 weeks), transdermal systems (patches, gels, solutions) or subcutaneous pallets (tab. II).

TABLE II

Route of administration, dosage, adverse events and monitoring of treatment with testosterone

Testosterone	Administration/Dose	Adverse events/ Disadvantages	Monitoring
Testosterone enantat/ cipionat	75-100 mg / 7 days or 150-200 mg / 14-21 days i. m.	wide fluctuations in serum testosterone levels	testosterone level at the middle interval between 2 injection
Testosterone undecanoat inj.	1000 mg i. m every 12-14 weeks	an enhancement at dose administration	immediately until the next injection
Testosterone non- scrotal patches	5-10 mg/ day	local irritation	at 3-12 hours after application
Testosterone gel	50-100mg/day	transfer during close contact	anytime (> 7 days after initiation)
Buccal testosterone	30mg /day	taste changes	immediately
Oral Testosterone Undecanoat	40-80mg x 2-3/day, during meals	digestives effects	at 3-5 hours after administration
Testosterone implants	4-6 implants of 200 mg, every 4-6 month	risk of extrusion or infection	at 3-5 hours after administration

Monitoring of testosterone treatment is recommended:

- first, at three months from therapy initiation, and then annually;

- determination of hematocrit (Ht); Ht > 52%-54% during the treatment is an indication of stopping the administration of testosterone, assessment of hypoxia and sleep-apnea**,** and after normalization of Ht restarting with lower doses of testosterone (2,9).

- BMD by DXA is repeated every 12-24 months in hypogonadal men with osteoporosis or fragility fractures;

- digital rectal examination and PSA checking are performed before treatment, at 3 months, and then in accordance with guideline for prostate cancer screening depending on age; urological evaluation is necessary if :

- PSA > 4 ng / ml

- PSA increase of more than 1.4 ng / ml within any 12 month period of testosterone treatment
- PSA velocity of more than 0.4 ng / ml / year, using PSA level after 6 month of testosterone administration as reference (only if PSA data are available for at least 2 years)
- Score for prostatic symptoms > 19 (AUA- American Urology Association or IPSS-International Prostate Symptoms Score - Europe)

Positive effects of testosterone administration are translated by improving mood, well-being and erectile function, or erectile response at phosphodiesterase 5 inhibitors administration, increasing of muscle mass and strength, especially in the upper limbs, decreasing of abdominal fat, increasing of bone mass. Short-acting testosterone preparations are preferred because it can be immediately interrupted if side effects occur.

Testosterone therapy in ageing men with hypogonadism is indicated only if the positive effects outweigh the risks, and after patient information about treatment risks and benefits.

Conditions in which testosterone administration is associated with increased risk of adverse effects:

- very high risk of serious adverse outcomes in metastatic prostate cancer and breast cancer
- moderate to high risk of adverse outcomes in unevaluated prostate nodule or indurations, or unexplained elevations of PSA (>4 ng/ml), Ht >50%, severe lower urinary tract symptoms, uncontrolled or poorly controlled congestive heart failure (class III, IV), severe, not treated sleep apnea (1,2).

In young patients, the goal testosterone concentration is midlevel of normal; at ageing patients, the goal is lower level of normal. There is no basis for dose escalations in pursuit of greater efficacy, and the practice may increase the risk of side effects. The vitality, energy and libido are ameliorated in the first 3 months of treatment, but the effect on body composition is evident latter, and is related directly with the testosterone level.

Adverse events for which there is evidence of association with testosterone administration:

- male pattern balding, acne
- gynecomastia - may exist before treatment
- induction or worsening of obstructive sleep apnoea
- worsening of Benign Prostate Hyperplasia (BPH)
- detection of subclinical prostate cancer, growth of metastatic prostate cancer;
- increased hematocrit
- reduced sperm production and infertility
- cardiovascular events (1, 2, 10).

EFFECTS OF LOW TESTOSTERONE AT VARIOUS ORGANS AND SYSTEMS; POSITIVE AND NEGATIVE EFFECTS OF TRT IN AGING MALES

Sexual function

Low testosterone reduces libido but the effect on erectile function is less obvious; erectile dysfunction is associated with low testosterone only among men with high luteinizing hormone (LH) levels. There are evidences suggesting therapeutic synergism with combined use of testosterone and phosphodiesterase-5 (PDE) inhibitors in hypogonadal or borderline eugonadal men (9, 13, 14).

Prostate cancer and BPH

There is no conclusive evidence that testosterone therapy increases the risk of prostate cancer. It is certain that testosterone stimulates growth and worsening of

symptoms in patients with advanced or metastatic prostate cancer. On the other hand, there are studies indicating that the aggressiveness of prostate cancer is higher in patients with low testosterone. For this reason, it is recommended at least one digital prostate exam and PSA evaluation before initiation of androgen therapy.

Also an IPSS > 21 or > 19 for AUA lower urinary tract symptoms (LUTS) are relative contraindication to androgen therapy. Contraindication is not maintained after treatment of prostatic pathology (14, 15). Rectal digital examination and PSA checking are indicated every 3-6 months at the beginning of treatment, and then annually.

Cognition, mood and energy

Some studies found benefits in improving spatial ability, verbal fluency, and working memory in elderly men. In a meta-analysis reviewing the effects on depression, testosterone therapy was found to have beneficial effects on mood and depression (10, 16).

Bone metabolism,
bone mass and fractures

The prevalence of osteoporosis in hypogonadal males is 2-fold increased compared with eugonadal males. Testosterone administration improves bone mass after aromatization to estradiol: spinal BMD increased by 8%. Effects on femoral neck are inconclusive. No fractures studies have been reported. Aging hypogonadism is associated also with vitamin D deficiency but the clinical significance of this relanshionship has to be investigated (10, 13, 17).

Body composition,
muscle strength and risk of falling

Interventional studies indicate an improvement in body composition with an increase in lean mass and decrease in fat mass after administration of testosterone in hypogonadal patients; it seems that the risk of falling by improving mobility is also reduced by administration of testosterone, although the mechanisms involved are not clear (10, 13).

Obesity

In MMAS study, average Body Mass Index (BMI) was 28.5 to 31.5 kg/m² for eugonadals and respective hypogonadals. 20-64% of obese men have low total and free testosterone levels, and low levels are associated with insulin resistance, metabolic syndrome and type 2 diabetes. The exact mechanism of the interrelationship between obesity and low testosterone is related to reduced abdominal lipolysis in case of androgenic deficit, increased visceral fat determining increase aromatase production, with increasing testosterone to oestrogen conversion and pituitary inhibition. Androgen replacement therapy reduces fat mass and increases lean body mass, with no overall changes in body weight (9, 10, 13, 18).

Lipid metabolism

Hypogonadal men have increased levels of total cholesterol and triglycerides (15). TRT decreases total cholesterol in men with lower testosterone levels, with no effect on triglycerides level (19); the effect of TRT in elderly men on LDL-C and HDL-C is controversial. Supraphysiological testosterone levels induce an increase in LDL-C and decrease in HDL-C levels, and increase the risk of cardiovascular disease.

Metabolic Syndrome
and Diabetes Mellitus

Epidemiological evidence from several longitudinal population studies shows that low testosterone (T) is an independent risk factor for the development of both MetS and T2DM. Interaction between insulin resistance, visceral adiposity, and hypo-

gonadism is not sufficiently elucidated, but seems related to the increased production of aromatase, leptin levels and inflammatory cytokines (15, 18). Veterans of U.S. with prostate cancer and anti-androgenic therapy have a higher incidence of type 2 diabetes, myocardial infarction, stroke and sudden cardiac death, and acute antiandrogen-therapy reduces insulin sensitivity and strongly impairs glycemic control of men with T2DM. Prospective studies have shown that men with higher T levels had a 42% lower risk of T2DM. In men with type 2 diabetes, metabolic syndrome and hypogonadism, testosterone therapy improves insulin resistance, as measured by HOMA-IR and reduces HbA1 by approximately 0.7% by 18 months.

Thus, a vicious circle ensues in which MetS suppresses T biosynthesis and conversely, reduced T concentrations predispose and contribute to the onset of development of MetS and in turn obesity (15, 18, 20).

Based on this epidemiological evidence, current guidelines suggest that patients with clinical conditions associated with insulin resistance (obesity, T2DM, and MetS) should be screened for hypogonadism.

TESTOSTERONE THERAPY AND CARDIOVASCULAR SYSTEM

Antiarrhythmic effect

Testosterone has an antiarrhythmic effect due to the observation that a low testosterone causes QTc prolongation (increased incidence of ventricular arrhythmias), reversible by testosterone administration. This effect is explained by increasing expression of Kv1.5 K+ channels and L calcium channels (15, 21).

Testosterone and atherosclerosis

It exist an inverse correlation between testosterone concentration and thickness of the intima (as marker for preclinical atherosclerosis): on the one hand, the metabolic effects, the increasing of the local inflammatory response (IL6, hCRP, TNF, IL-1B), apoptosis and lowering vascular smooth muscle cell stability of a low testosterone are cardiovascular risk factors, and on the other hand atherosclerosis determines low testicle perfusion and low testosterone secretion (15, 20).

Another effect of testosterone is as vascular vasodilator, independent of nitric oxide, possibly by inhibiting L-type and T-type calcium channels. (20,21). In the same way, men with lower levels of endogenous testosterone are more prone to develop coronary artery disease (CAD) during their lifetime, and it exists a correlation between the severity of CAD and the degree of testosterone deficiency (20,22). TRT is positively associated with a significant increase in treadmill test duration and time to 1mm ST segment depression in men with stable coronary artery disease. TRT improves the angina threshold (14, 20) and reduces the infarct size comparative with that in hypogonadal subjects not treated (21). Controversy, there are studies (in rats) that show that exogenous testosterone exacerbate atherosclerosis and it exist a proapoptotic effect of testosterone (21, 23). In his study, Glueck has demonstrated that men with coagulability problems (factor V Leiden mutation or elevated homocysteine) have an increased risk for thromboembolism at 3 months after androgen therapy initiation (24). Prospective epidemiological studies are needed to analyze in detail the association between coronary heart disease and endogenous bioavailable testosterone (20, 23).

Heart failure

A key feature of congestive heart failure (CHF) is metabolic shift toward catabolism,

with activation of neuroendocrine and inflammatory pathways. The result is worsening of exercise intolerance. Studies show that patients with heart failure have low levels of total and free testosterone, and that with worsening severity of cardiac failure, there is a significant stepwise decrease in testosterone concentration (20, 25). Furthermore, it was hypothesized that the only predictor of the degree of deterioration of exercise capacity (using peak VO2, peak-VO2 pulse) is the magnitude of testosterone levels reduction. This means that the association between serum testosterone and aerobic exercise capacity is independent of the severity of heart failure, the use of beta-blockers or chronotropic response to exercise (20). Testosterone therapy in cardiac failure improves exercise capacity by 0.5 DS, not by effect on left ventricular ejection fraction, but by a peripheral direct mechanism on the skeletal muscles, by causing a shift toward more type I muscle fibers in patients with CHF. Low testosterone in cardiac failure patients correlates negatively with exercise capacity and is associated with a worse prognosis and higher mortality, and TRT is associated with a significant improvement in exercise capacity (20, 25).

MORTALITY

Men with low testosterone are at risk of premature death; testosterone value below 8 mmol / l increases mortality three times, and five times the cancers risk (28), and a decreased testosterone with 2.1 DS is associated with an increased risk of cardiovascular mortality by 25% (20). Low testosterone is associated with increased mortality in diabetic patients, and TRT improves the survival (13, 20, 23, 26, 27, 28).

Cardiovascular risk and androgen therapy is a very controversial topic because an optimal level of testosterone is a biomarker for survival, but the androgen therapy may increases the risk of nonfatal MI. There are a lot of studies that find no increase in the cardiovascular events in case of testosterone replacement therapy, but pharmaceuticals companies support many of them. Studies that had alert about the cardiovascular risk are also critical because no one had as endpoint the cardiovascular risk and the TRT, most studies involved have small cohorts with a small number of events, the study population was old (over 70 years), with cardiac problems, the doses of testosterone were very high (100mg/day) (29), or the alternative study drug was an PDE inhibitor that provide cardiovascular-protective effect (30, 31), or the impact of symptoms as an indication for TRT prescribing was not analyzed because is well-known that the presence of erectile dysfunction is an independent cardiovascular risk factor (increase the incidence of CV events with more than 50%)(30, 31, 32).

This apparent discordance between low testosterone as cardiovascular risk factor and the potential cardiovascular risk of testosterone replacement therapy could be explained by Corrona's concept of **"low testosterone syndrome"** - an adaptive response in order to be more resilient to a pathological condition (cardiovascular frailty: T2DM, CVD); the low testosterone is only a marker for poor health, for saving energy (less physical and sexual activity) and to protect species (low fertility) (14).

Another explanation for these discrepancies between low levels of testosterone as cardiovascular risk factor and the cardiovascular risk in case of TRT, could be that endogenous testosterone is beneficial, but exogenous testosterone and its metabolites could be harmful, the degree of testosterone deficiency is not similar in late onset hypogonadism (LOH) versus Klinefelter

syndrome, or induced hypogonadism in prostate cancer, auto medication and self increasing doses (14).

If we want to respond to this debate: Is low testosterone level in CVD a positive consequence of the body trying to decrease unnecessary energy (and in this situation the treatment might be deleterious for overall and cardiovascular health) or it represent**s** a pathophysiological factor in the CVD (in this situation the treatment is recommended)**,** we need large prospective placebo-controlled randomized trials such as the Women's Health Initiative to determine definitively the cardiovascular risks of TRT. Until this**,** physicians and patients should have a conversation about the risks and benefits of using testosterone, especially in patients who have pre-existing heart disease (32, 33).

In conclusion**,** LOH is frequently co morbid with almost all severe and chronic diseases; clinicians have to look for hypogonadism in men with Met**S**, T2DM or CV disease**,** and conversely to look for metabolic and CV co morbidities when hypogonadism is found. TRT is able to improve central obesity (subjects with MetS), glycometabolic control and insulin resistance, ameliorate exercise capacity and survival. Appropriately prescribed testosterone is undoubtedly beneficial**,** but caution needs to be taken in certain situations**,** as the associated health/benefits of TRT **to outweigh** the potential increased risk of cardiovascular-related events.

IMPLEMENTING EBUS TBNA: FIST EXPERIENCE AND REVIEW OF LITERATURE (Abstract): Lung cancer has a very dismal prognosis and careful diagnosis and staging is of outmost importance. EBUS has become a cornerstone investigation for diagnosis and staging and current guidelines stress that there is a steep learning curve when introducing this technique in practice (only 30 procedures are considered necessary). Over a period of 10 months a total of 21 patients have been addressed to our unit for an EBUS TBNA procedure. Only three were referred for staging purposes (for lung, digestive and cervix cancers) the others being primary diagnostic approaches where simpler procedures had previously failed. Procedures were initially performed under local anesthesia (3 cases) then under general anesthesia and jet ventilation using a laryngeal mask approach. Mediastinal lymph node group 7 was the most frequent target (9 cases) followed by group 4R (8 cases) and peribronchial tumoral processes (7 cases); one case did not required any needle-aspiration. On average each examination resulted in the sampling of 1.4 targets. There were no significant procedure related severe adverse events. Although 21 G cytology needles were used, adequate histological samples were obtained for 11 cases and cytology was the examination of choice for 9 cases. The pathology/cytology results were retrospectively assessed as satisfactory for 15 cases (confirmed neoplastic or other disease) and inconclusive for 5 cases. Non neoplastic disorders were represented by sarcoidosis, tuberculosis and bronchogenic cyst (3 cases). The procedure can be considered fast and safe; trained pathology personnel play an extremely important role; presently referrals are rare for staging purposes. **Keywords:** LUNG CANCER, DIAGNOSIS, STAGING, EBUS TBNA, ENDOSCOPIC ULTRASOUND.

Lung cancer has a very dismal prognosis and careful diagnosis and staging are of outmost importance in choosing the optimum therapeutic approach - surgery, chemotherapy, radiotherapy or combinations. Assessing the N2 nodes status in non small cell lung cancer patients has become essential as multimodal therapeutic approaches became available. Despite significant advances in mediastinum imaging, careful clinical lymph node staging is preferable in guiding therapy as frequently radiologic criteria may prove unreliable. Overall sensitivities of 75% and 84% and

specificities of 82% and 89% were cited for CT and PET/CT respectively (1, 2). Therefore invasive (i.e. histological proven) mediastinal staging should be the norm if N2 or N3 disease is suspected (3).

Since the 1954 initial report mediastinoscopy quickly became the gold standard for invasive mediastinal assessment with a sensitivity of 81% and a negative predictive value of 91% (1, 4). It has been partially superseded by minimal invasive approaches as endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS). These became cornerstone investigations for diagnosis and staging as results are comparable to mediastinoscopy with a much lower adverse event rate and cost. A pooled specificity of 1.00 (95% CI 0.92 to 1.00) and sensitivity of 0.88 (95% CI 0.79 to 0.94) has been reported for EBUS TBNA as far as mediastinal lymph node staging is concerned (5).

Similar values have been reported for endoscopic ultrasound (EUS) approaches for non-small cell cancer staging(6). A combination of both techniques have been proved to be superior compared with mediastinoscopy with a combined sensitivity of 94 % *vs.* 79 % (7).

A recent meta analysis(8) reported a negative likelihood ratio of around 15 % a value suggesting that there is still a role for more invasive approaches in selected cases.

However EBUS/EUS is considered as the first intent approach - considering the fast patient recovery since only minimal anesthesia is required and no significant surgical trauma is involved. Most mediastinal lymph nodes groups can be sampled (with the exception of groups 5 and 6 (9, 10) which can be usually reached by VATS). Its role is clearly expanding as more potential targets are considered – such as left adrenal, left liver lobe or thyroid gland (11). Apart from versatility, ultrasound imaging may contribute with additional data to CT appearance to assess node involvement. Indeed, apart a small diameter over 10 mm and a round shape (features usually assessed on CT) heterogeneous echogenity and absence of central hilar structure were recently mentioned as predictors for malignant involvement (12). Furthermore EBUS TBNA can be readily repeated if inadequate samples are obtained or for the purpose of disease progression monitoring as no significant sequelae are expected. There were some concerns when comparing EBUS to mediastinoscopy as far as yield was concerned. Recent data suggests that a usual approach entailing at least 3 passes per target will return an acceptable sample for pathology and molecular examinations. This will ensure high (over 95%) sensitivity and accuracy values for mediastinal staging (13).

Current guidelines stress that there is a steep learning curve when introducing this technique in practice – on a yearly basis significant improvement is seen after 25 procedures and diminishing returns are encountered after 50 procedures(14).

Since the introduction of EBUS TBNA in our unit some particular issues and pitfalls became apparent and we report on our initial experience.

MATERIAL AND METHOD

A total of 21 patients have been assessed using an EBUS TBNA approach over a year starting with June 2013; this was performed using an OLYMPUS EUME1 on an OLYMPUS EVIS EXERA III infrastructure.

Only three patients were referred for staging purposes (for lung, digestive and cervix cancers). The rest of the procedures were primary diagnostic approaches where simpler less invasive procedures had previ-

ously failed or were judged to be potentially useless (mainly bronchoscopy and transthoracic approaches).

METHODOLOGY

Standard preprocedure requirements included – complete medical history, signed informed consent, coagulation assessment, EKG, chest CT, per month for 12 hours.

Main contraindications considered were: significant arrhythmias or cardiac conditions, high bleeding risk (thrombocytopenia, anticoagulant / antiplatelet agents, renal failure), acute respiratory failure. There were no absolute contraindication; two procedures were postponed until antiplatelet agents effects wore off (seven days). No antibiotic prophylaxis was routinely considered although seven cases received postprocedure antibiotherapy.

Initially potentiated local anesthesia was used (three cases) then a switch was made to general anesthesia under high frequency jet ventilation administered on laryngeal mask (this approach ensured good working conditions and patient comfort). Median working time was 60 minutes (anesthesia time included).

EBUS examination was preceded by standard bronchoscopy to exclude evident bronchial lesions as the EBUS scope has a lower resolution image and a narrow 30 degree angled field of view. Once the EBUS scope was passed into trachea the convex ultrasound probe was brought in contact with the lateral tracheal wall (an inflatable balloon was used to improve contact). Main lymph nodes groups were identified (hypo echoic and Doppler negative) and assessed (shape and size) using the following approaches/landmarks using a N3 to N1 approach:

2R, trachea, superior vena cava, brachiocephalic veins

2L, trachea, above the aortic arch

4R, trachea, superior vena cava, below the azygos vein (Fig. 1)

4L, trachea, aortic arch, pulmonary artery

7, right or left main bronchus

10R, right main bronchus, interlobar pulmonary artery branch (Fig. 2)

10L, left main bronchus, left pulmonary artery

11R, intermediary trunk, interlobar pulmonary artery branch

11L, distal left main bronchus, interlobar pulmonary artery branch

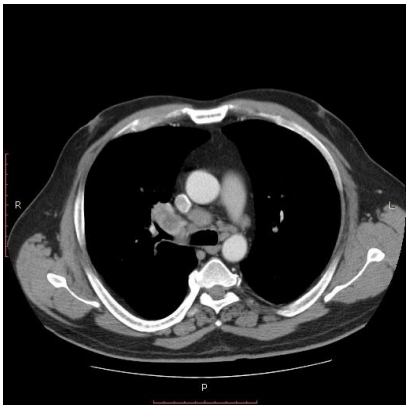

Fig. 1. Groups 10R and 4R lymph nodes – CT section

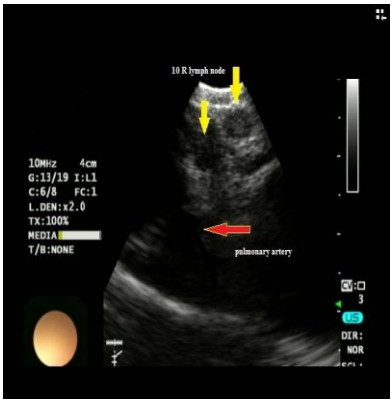

Fig. 2. Group 10 R lymph node – echographic view

Abnormal nodes were identified on CT. Identified lymph on the endoechographic images were punctured under ultrasound control using 21 G Olympus needles; at least three passes were done per target as recommended. Rapid on site cytology assessment although available was not considered necessary (16). Aspirated specimens were discharged in 90 degrees alcohol – this approach while convenient as it provided immediate feedback caused some difficulties for pathology personnel as instantly formed large blood clots obscured aspirated fragments. Therefore it was later changed to saline followed fixing by addition of the same volume of 97% alcohol. Cytoblocks were obtained after centrifugation and inclusion in a support matrix and then processed as regular biopsies for Paraffin embedding.

RESULTS

Mediastinal lymph node group 7 was the most frequent target (9 cases) followed by group 4R (8 cases) and peribronchial processes (7 cases). Targets also included groups 4L, 10 and 11 on both sides. Each examination involved an average of 1.4 targets to a total of 29.

There were no procedure associated adverse events in our group except for two cases. In first case the procedure was prematurely stopped due to anesthesia issues. The second was a foreign body situation - distal latex balloon disengaged; it was promptly recovered using a biopsy forceps and a video bronchoscope. Minor procedural bleeding was not considered a significant adverse event and did not require any specific intervention. Recovery was fast; all patients were returned to the ward by next day and usually discharged soon after.

Estimated expenditure was around 350 euro per procedure - mainly due to disposable equipment and standard short hospitalization costs.

Although 21 G cytology needles were used adequate histological samples, albeit small were obtained for 11 cases and cytology results were available for 9 cases.

For one case no invasive approach was needed as ultrasound examination revealed a small diameter adenopathy (suspicious on anterior CT scan).

The pathology/cytology results were retrospectively assessed as satisfactory for 15 cases (confirmed neoplastic or other disease) and inconclusive for 5 cases (non specific aspects except lymphoid tissue).

These were referred for more invasive approaches if there was a high index of suspicion.

Non neoplastic disorders were represented by sarcoidosis, tuberculosis and bronchogenic cyst (3 cases).

DISCUSSION

While the optimum number of stations to be assessed during an EBUS examination is still open to debate it is generally considered that sampling more than two may improve staging accuracy (17). Still as for our case series the average was 1.4 stations per procedure – a figure which must be interpreted taking account of the diagnostic purpose of the approach. More often than not the patient had an imagistically assessed stage IV disease which precluded or made inadequate invasive approaches such as thoracotomy and also made unnecessary N staging.

Group 7 was the most frequent target in our group and could have probably been reached by conventional TBNA – still EBUS was preferred as it allowed multiple

target assessment and cost was roughly similar. Furthermore recent data suggests conventional TBNA skill improvement after implementing EBUS training (18).

While peripheral lung nodules may not always be assessed by EBUS this approach proved useful in selected cases (seven for our group) as have been reported before; all seven peripheral pulmonary nodules/masses were positively diagnosed(19).

EBUS-TBNA complications were previously reported – agitation, post-procedural cough, hypoxia, laryngeal injury, fever, bacteremia/infection, pneumothorax, mediastinal abscess, laryngospasm/ laryngeal edema, bronchospasm; their frequency was estimated around 1.4%. The main risk factor was considered the presence of a concurrent transbronchial lung biopsy (20). There were no procedure related complications in our group. This may partly be explained by the general anesthesia/high frequency jet ventilation approach we used which circumvented upper airways reactions and total refrain from trans bronchial lung biopsies. Post procedure antibiotherapy was prescribed if purulent bronchial secretions had been found.

Fast recovery – due to either low anesthesia requirements or low surgical trauma involved may imply a special role for EBUS TBNA for frail patients for whom a more invasive approach may associate a significant vital risk. This is also suggested by the fact that no patient was refused once addressed as their concurrent conditions were not considered to be absolute contraindications. There was one case for which active watch was preferred as available clinical data was suggestive for reactive inflammatory adenopathy; chest CT repeated after three months showed complete resolution (21).

As far as results were concerned 15 procedures returned positive diagnosis – five were considered inconclusive. Given the low negative likelihood ratio (8) and the high suspicion threshold we decided to refer the patients for subsequent more aggressive approaches. Still we consider 15 positive diagnoses to be encouraging given the fact that histological samples were available in only 11 cases. This was probably possible because EBUS samples proved to be generally suitable to immunhistochemistry assays either as core biopsies or as cell blocks (22, 23).

There were some non neoplastic conditions in our group. While tubercular lymph node involvement and bronchogenic cysts are not usually explored by TBNA (mainly because late complications such as fistulae may develop) these were incidental findings while suspecting malignancy. On the other hand sarcoidosis node involvement was suspected and confirmed for one patient; EBUS TBNA was preferred as there were no significant endobronchial lesions and no infiltrates on chest CT. Because of group 4R involvement which is particularly difficult to assess on an unguided approach; current practice strongly encourages the use of EBUS TBNA over TBNA for these cases(24).

More while transbronchial lung biopsies seem to have the highest diagnostic yield as a standalone procedure adding EBUS TBNA may improve the figure to over 80% and is probably superior to conventional TBNA (25) as recent data suggests a particular appearance for sarcoid lymph nodes – distinct margins and granular appearance(26).

CONCLUSIONS

EBUS TBNA may be used for diagnos-

tic and staging purposes in bronchopulmonary carcinoma patients as it can reliable reach mediastinal node stations (excepting groups 5, 6, 8, 9) and peribronchial masses.

It can be considered a reasonably fast procedure with an excellent safety profile, acceptable cost as compared to mediastinoscopy and a particularly fast post procedure recovery.

General anesthesia under jet ventilation greatly improves comfort for both the patient and the medical team but the procedure may be performed reasonably well under local anesthesia.

Trained pathology personnel play an extremely important role and sample management protocol should be adequate for imunhistochemistry assays.

Although diagnostic yield is encouraging for both neoplastic and non neoplastic conditions more invasive approaches may still be necessary as negative predictive power is low.

The procedure is little known to other health professionals and thus referrals are rare for staging purposes – more publicity would probably be useful.

RED CELL DISTRIBUTION WIDTH (RDW) - A POTENTIAL PROGNOSIS FACTOR IN MALIGNANT MELANOMA (Abstract): Although malignant melanoma accounts for less than 5% of all cancers, it is one of the most aggressive types of cancer, associated with a poor outcome. Survival rates significantly vary according to stage and even within the same stage there are significant survival differences. The **aim** of this study was to assess the role of red cell distribution width (RDW) as a potential prognosis factor for malignant melanoma. Also, this analysis aims to determine average survival and the time until relapse/progression of the disease in patients with malignant melanoma treated at the Regional Institute of Oncology Iasi (IRO) between 2013 and 2016. **Materials and methods**: We performed a retrospective analysis of melanoma patients treated in the IRO between 2013 and 2016. We collected several parameters including age, sex, tumor localization, clinical and pathological stage, Breslow Index, Clark level, ulceration and detailed therapeutic management. We then analyzed each parameter to assess its impact on progression-free survival and overall survival. **Results**: We identified RDW as a significant prognosis marker, with worse outcome for patients with abnormal RDW values. Additionally, tumor localization, Clark level, Breslow index and cancer stage also showed prognosis value. **Conclusions:** RDW is a useful, inexpensive prognosis marker that can better predict survival. Prospective studies are required for confirming the findings of the present analysis. **Keywords**: MELANOMA, RED CELL DISTRIBUTION WIDTH, PROGRESSION FREE-SURVIVAL, OVERALL SURVIVAL.

Along with the worldwide population ageing trend (1), there is a progressive increase in the incidence of a large number of cancers, such as colon cancer, hepatocarcinoma (2), breast cancer and melanoma (3). Although malignant melanoma currently represents less than 5% of cancers, it is estimated that in 2014 this neoplasia was responsible for over 9,000 deaths in the United States alone (4), being considered one of the most aggressive types of cancer and generally associated with a bad prognosis (5). Furthermore, epidemiological reports from recent years have shown there is a tendency towards the decrease of the median age of diagnosis, together with a significant increase in melanoma incidence in males (6). In Europe, the countries with the highest number of melanoma cases are in Germany, Switzerland, Norway, Denmark and Iceland (5). In Romania, melanoma is the second most frequent type of

cancer in individuals aged 15-29 years, with an increase rate of 4% per year (7).

Traditionally, malignant melanoma is believed to be a cancer associated with an unfavorable outcome. With the improvement of surgical and radiotherapy techniques, along with the introduction of immune therapy and the systematic testing of the BRAF mutation, new therapeutic approaches have significantly improved the quality and life expectancy of patients with metastatic malignant melanoma (8). Five-year survival is estimated to be 62% for patients with lymph node invasion at diagnosis and 18% for those diagnosed directly in the metastatic stage (9), results which are now well above the epidemiological reports of previous decades. However, survival assessment remains difficult (10) and there are significant variations within the same disease stage (11). Also, similar to other types of tumors (12), there are certain clinical situations where diagnosis and staging are difficult due to lack of symptom specificity and aggressiveness of the disease. In addition to TNM staging (tumor size, lymph node invasion, and presence of metastasis) recommended by the American Committee Against Cancer (AJCC), which remains the most prevalent method of assessing prognosis (13) for many cancer types (14), there are certain "classical" prognosis factors considered to have an independent impact on survival in malignant melanoma. Of these, male gender, advanced age, localization on the head, neck or trunk, increased Breslow and Clark levels, presence of ulceration, and increased mitotic rate (15) are associated with a more bleak prognosis, regardless of the stage at diagnosis.

Together with a significant increase in the number of preclinical and clinical cancer studies (16) that aim to improve diagnosis or find new methods of treatment (17), , more and more new potential prognosis factors have been assessed which has led to the identification of some parameters that can predict significant modifications of the length of survival and have a predictive role in the response to treatment. Some of these, such as the presence of BRAF mutation, sentinel lymph node status, LDH level or S100 protein, are already used in the clinical setting (18), whereas others such as vitamin D (19), lymphocyte infiltration (20), or genetic modifications identified by means of "next generation sequencing" (NGS) techniques (11) have not yet gathered sufficient scientific evidence or cannot be implemented on a large scale due to significant additional costs. As such, there is still a need to identify new prognostic factors that are easy to assess for malignant melanoma to individualize patient prognosis.

Red cell distribution width (RDW) is a commonly-assessed parameter included automatically in the complete blood count of patients; it determines the presence of variations in the size or volume of red blood cells (21). In recent years, it has been assessed as a prognosis factor in several types of solid tumors such as lung (22), prostate (23), endometrial (24) or hepatic (25) cancer and it has been identified as a relevant prognosis factor for all these localizations. However, to the authors' knowledge, RDW has not been previously assessed as a prognostic factor for patients diagnosed with malignant melanoma.

The **aim** of this paper is to assess the role of RDW as a potential prognosis factor for malignant melanoma. Also, this analysis aims to determine average survival and the time until relapse/progression of the

disease in patients with malignant melanoma treated at the Regional Institute of Oncology Iasi between 2013 and 2016. One other aim is to confirm the value of established prognostic factors in assessing survival for patients included in the present analysis.

MATERIAL AND METHODS

We performed a retrospective analysis on all cases of cutaneous melanoma treated at the Regional Institute of Oncology (IRO) Iași between 2013 and 2016. IRO is a tertiary medical unit specialized in diagnosing and treating both hematological and solid malignancies that serves as a reference center for Moldova, the north-eastern region of Romania. In IRO, melanoma diagnosis is based of pathology assessment of tissue and staging is determined based on CT, MRI, or PET-CT imaging studies. All cancers diagnosed in IRO are staged according to AJCC's TNM system. Performance status is routinely assessed by means of the World Health Organization approved Eastern Cooperative Oncology Group (ECOG) PS scale.

Inclusion criteria for the present analysis were histological confirmation of cutaneous melanoma (incisional/excisional biopsy or surgery), receiving local or systemic treatment in IRO, a performance status ≤ 2 at the time of the diagnosis and being over 18 years of age.

Exclusion criteria were: a history of a prior malignancy (non-melanoma skin cancer excluded), chemo/radiotherapy prior to the initiation of melanoma treatment, non-cutaneous melanoma localization, doing treatment and follow-up in another medical unit and performance status > 2.

Patient records were accessed by means of the hospital's electronic database. We collected a series of patient's characteristics, tumor and clinical data for each case. Parameters were structured as follows: demographic data: sex, age, urban/rural residence, clinical data: tumor localization, clinical TNM stage, presence and localization of metastasis, ECOG performance status, biochemical data (before treatment): LDH, RDW, platelet distribution width (PDW), white blood cell count, hemoglobin, histology and molecular biology data: Clark level, Breslow index, presence/absence of ulceration, pathology TNM stage, S100, BRAF, treatment data: surgery, radiotherapy, first-line and second-line anti-cancer systemic treatment, toxicity of treatment, survival data: date of diagnosis, recurrence date (if applicable), overall survival

Statistical evaluation was performed using *SPSS version 20.0* software. Unpaired Student's *t*-test, Chi-squared, Kaplan-Meyer survival curve and Fischer exact test were used according to data type. For each collected parameter, we assessed its potential impact on overall survival. Statistical significance was defined as $p < 0.05$; variables were considered independent for the statistical analysis; continuous data was expressed as mean ± standard error.

RESULTS

Descriptive analysis

Of the 120 patients identified in the electronic database, 75% of the patients fulfilled the inclusion criteria. 25% of the patients were not included in the analysis because they had non-cutaneous melanoma or because they either refused treatment of received it in a different hospital.

In our study group, the male: female ratio was 1.04:1, with 51.1% male and 48.9% female. Average age at diagnosis was 58.56

years, with a median of 59 years. Most patients were younger than 65 at diagnosis (61 out of the 90 patients) and lived in the urban area (74.4%). Regarding localization, most primary tumors were in the lower limbs (32.2%), followed by posterior thorax (22.2%), anterior thorax (12.2%) and abdomen (11.1%). From a clinical staging point of view, most patients were diagnosed in stage II disease, with 18 patients being diagnosed in stage IIA, 13 in stage IIB and 12 in stage IIC. The rest were most often diagnosed in stage III (27.7% patients) or stage IV (7.77% patients) of the disease. Only four patients were diagnosed in stage I. Most frequent metastatic sites included brain, lung liver and bone.

Regarding performance status, most patients (91.1%) had ECOG = 1 at diagnosis, whereas 4.44% were ECOG = 0 and 4.44% were ECOG = 2. Biochemical assessment before treatment initiation indicated that 38.9% of the patients had increased LDH levels, 36.6% had lymphocytosis, 13.3% had a decreased monocyte count, and 24.4% had grade I or II anemia.

Pathology and molecular biology analysis of the biopsy/surgical piece revealed that most melanomas had a Breslow index of over 4 mm (44.4%) and only 2 patients had a Breslow index < 1 mm. Similarly, Clark levels were most often IV (27%) or V (25%), with only one patient being assessed as a Clark I. More than half of the patients (56.7%) presented ulceration at diagnosis and most cases were upstaged after tissue analysis (cTNM vs. pTNM). Regarding BRAF mutation, it was only tested in 15 patients, 6 of which were found to be BRAF positive. S100B protein was increased in 18.8% of patients, with normal levels in 74 patients.

Regarding treatment data, most of the patients underwent surgery as a first-line localized therapy option. Throughout the course of the disease, however, almost all patients underwent curative or palliative surgery and most of them benefited more than once from this approach (96.6% of patients with 152 surgical procedures performed). Adjuvant therapy included interferon in three cases and radiotherapy if positive margins, although most localized melanomas were simply followed-up periodically. Most patients in stage II or III disease quickly developed local or generalized recurrences and received either local therapy (second surgery and/or radiotherapy) or first-line systemic therapy. Radiotherapy was recommended in 23.2% of patients, either at the primary site (12.2% of patients) or for brain metastases (11.1% of patients). Dacarbazine was the preferred first-line chemotherapy choice in all cases. Second-line chemotherapy options were Carboplatin (10%), Cisplatin and Paclitaxel (4.44%) or Temozolamide (2.22%). One in four patients (24%) could not complete the projected number of cycles due to inacceptable drug toxicity/ One patient refused systemic treatment after being diagnosed with systemic recurrence six months after surgery.

Maximum progression-free survival recorded was 191 months; survival time had a minimum of one month and an average of 42 months. Average progression-free survival was 22.46 months.

Prognosis factors

After analyzing the potential relevance as a prognosis factor, five of the assessed parameters were found to be associated with prognostic variations: primary tumor localization, Breslow index, Clark level, stage and RDW values.

Primary tumor localization was associated with a better outcome if the tumors were in the limbs when compared with abdominal or thoracic melanoma (p=0,043 for limb vs. abdominal melanoma and p=0,036 and p = 0,021 for limb melanoma versus anterior and posterior thoracic melanoma). Average survival for a patient with melanoma on the abdominal cutaneous surface was 29 months and 26 months for thoracic melanoma. In contrast, lower-limb melanoma patients had an average survival of 36 months and upper-limb melanoma patients had an average survival of 77 months, a statistically significant difference.

Breslow index was found to be a significant prognosis factor, with better outcome for a Breslow < 1 mm when compared with a Breslow > 2.1 mm (p=0,008). Recurrence-free interval was 142 months for patients with Breslow < 1 and progression-free survival (PFS) abruptly decreases as the Breslow index is higher, with a 48-months value for a 1-2 mm Breslow index. Similarly, Clark level also showed prognosis value, with statistically different survival averages between level III when compared with level IV and level V (p=0,006, p=0,010). Progression-free survival was 142 months for Clark I, with a progressive decrease of survival as Clark levels grow (23 months overall survival for Clark V).

In our analysis, stage had a significant prognosis value. Patents with clinically noticeable lymph node invasion (N = 33) had a worse outcome when compared with patients with negative lymph nodes (p<0,016). Among those without node involvement at diagnosis, 42.2% quickly presented with local or systemic relapse. Average survival was 21 months for patients with lymph node involvement and 46 months for those without. Patients diagnosed directly with stage IV disease had a worse prognosis when compared with localized or locally advanced disease (p=0.00038), with an average survival of seven months for metastatic disease. Stage had a statistically significant impact on survival, with stage IV patients that were associated with worse prognosis when compared with other stages (p=0,006, p=0,016, p=0,013 when compared with stage I, stage II and stage III disease).

RDW also had a significant prognosis value - patients with an RDW > 15% (increased) had a decreased survival time when compared with those with normal RDW values at diagnosis (p=0,030). Average survival was 33 months for patients with abnormal RDW values compared with 64.97 months for those with normal RDW values (fig. 1).

Several other factors were assessed in this analysis and showed little or no influence on prognosis. Although a small benefit was noted for females, distribution according to sex did not show statistically significant differences. Similarly, age distribution, LDH and S100 values were not shown to have prognosis values. A small benefit of survival (38 vs. 37 months) was shown for patients without tumor ulceration, but it don't reach statistical significance. Since generalized BRAF testing was only available in IRO in 2015, we could not assess the effects of BRAF mutations on survival. All patients in non-metastatic stages received surgery and first-line chemotherapy was in all cases Dacarbazine, so no comparison could be performed. Second-line chemotherapy was not initiated in all cases and no statistical differences were found between treatment protocols.

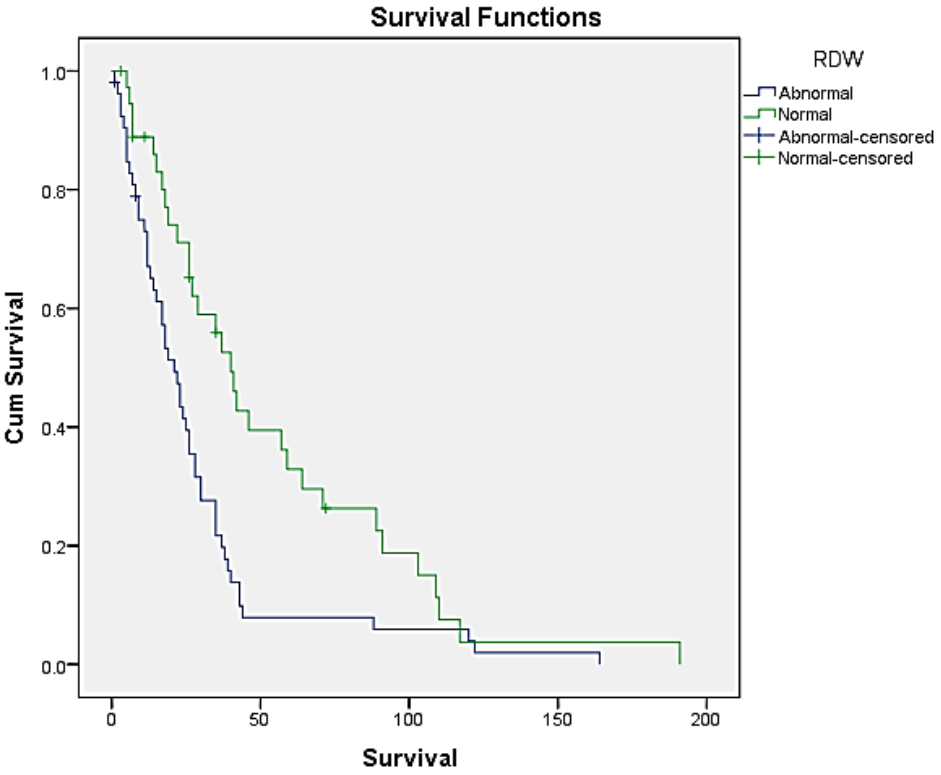

Fig. 1. Patient survival and RDW values before treatment initiation

DISCUSSION

The present retrospective study included 90 patients who received treatment in IRO Iasi. The maximum survival rate registered in this group was 191 months, with a mean survival of 42 months; progression-free survival was an average of 22.46 months. Gender did not have a significant influence on overall survival, although we noticed a numerical difference in favor of the female sex. Literature data is not consistent regarding the influence of gender on survival rate, although a study assessing 3,900 melanoma patients showed that women appear to have a better prognosis than males due to a protective factor that was not yet clearly identified (26). Our analysis did not identify a difference in gender survival, most likely due to the small number of patients included.

Regarding age as a prognostic factor, we did not identify any significant differences between patients. This is somewhat surprising, taking into account the fact that elderly have a tendency for self-neglect (27) and often have cognitive dysfunctions and other relevant comorbidities that can significantly delay and influence both diagnosis and treatment (28,29). However, we have interpreted this result because of patient selection - there is an inherent bias to choosing only patients that choose to receive treatment in a cancer institute and are fit enough to do so.

Similarly, the place of residence (urban versus rural dwellings) did not have a significant influence on survival, a result which is different from other literature data. According to several retrospective studies conducted in Canada, there was a higher incidence of melanoma reported in urban vs. rural areas. Researchers explained this by pointing out that people living in a city have easier access to see a dermatologist, which increases the chance of diagnosing atypical nevi with malignant potential and diagnosing melanoma in general, concluding that actually there is no real difference in prevalence in urban versus rural areas (30).

Primary anatomical localization was identified as a major prognosis factor, with significant statistical differences between melanoma of the extremities versus melanoma located on the abdomen and on the anterior and posterior thorax. In this analysis, we noted a significant survival advantage for patients diagnosed with melanoma in the limbs. These data is consistent with other literature data, considering that in a study of 2,500 patients, melanoma located on the neck, trunk and head had worse prognosis when compared with other sites (31).

Stratifying according to the Breslow Index showed a significant difference in survival rate, with longer survival for less invasive melanomas. An increase in the Breslow Index was associated with a worse outcome, with a steep decrease in recurrence-free survival for a 1-2 mm Breslow (48 months). According to the AJCC, in a study of 1.841 patients, the 10-year overall survival rate was 92% for Breslow Index 1, 80% for Breslow Index 2, 63% for Breslow Index 3 and 50 % for patients with the Breslow Index 4, consistent with the results of this analysis (32). Similar results were observed for the Clark level, with a progressively decreasing overall survival from Clark I (142 months) to Clark V (23 months).

Our data indicated the TNM stage was another relevant prognostic factor, with a significant increase in the risk melanoma recurrence or progression for those patients with positive lymph nodes at the time of diagnosis. Thus, average survival was 21 months for those with positive lymph nodes and 46 months for those with negative lymph nodes, regardless of the stage of the disease. According to literature data, lymph node invasion is a well-established prognostic factor with studies reporting that negative lymph node patients have a 76-90% PFS at 5 years, whereas those with positive lymph nodes have a PFS of 35-58% at 5 years (33). The presence of systemic disease at diagnosis is considered an independent prognosis factor with a mean survival of one year for stage IV patients according to one study (34). Our results fall in line with available data - in IRO, the survival of patients with metastatic malignant melanoma was 7 months.

RDW variations were associated with different outcomes. There was a statistically significant difference in survival for patients who had RDW above 15% (increased) when compared with those with normal RDW values. Average survival was 33 months for patients with increased RDW and 64.97 months for those with normal RDW prior to treatment initiation. In recent years, RDW has become an attractive prognosis factors and has been assessed in several types of tumors, showing that it can be used as an independent means for predicting survival. In a study of over 300 patients, Koma&colab. found RDW to accurately predict survival in lung cancer, not only for advanced, but also for localized stages of the disease (22). RDW was found to predict survival of patients

with pancreatic cancer in a study conducted in Turkey on a group of 104 patients (35). Also, in a Chinese study performed on a group of 608 patients, abnormal RDW values were correlated with a worse outcome in breast cancer patients (36).

Due to the characteristics of the present analysis, several factors considered predictive by international guidelines did not have any effect on survival. Thus, a definite correlation could not be made between the presence of ulceration and patient survival due to incomplete pathological staging (in some cases) and the small group of patients. In a study performed on a group of 423 patients in Spain, ulceration was significantly correlated with a decrease in both overall survival and PFS survival (37). Since routine BRAF mutation testing has been only recently introduced in IRO standards, the number of patients tested for BRAF mutation was too small to achieve a definite correlation. Also, we did not record significant differences in overall survival when stratifying by LDH or S100b protein level. A possible explanation for these findings would be reduced specificity of these markers (abnormal levels are also found in patients with hepatic, renal, various inflammatory and infectious diseases). Also, in this analysis we included patients diagnosed in all disease stages, whereas most studies that indicate these markers as prognosis factors were performed on stage IV patients. In a study on a group of 855 patients with melanoma, both LDH and S100b values were classified as independent prognostic factors for metastatic melanoma (38). However, other studies on these two markers were inconclusive (39).

The general research trend encourages and supports identifying new treatment methods, molecular biology or genetic risk factors and funds the development of novel drugs. However, some of the clinically used drugs and some of the already available markers might have surprising uses in different practical settings (40). Changing drug ratio for active combinations (41) or simply reanalyzing some of the markers at hand can lead to novel results and improve daily practice without additional costs.

Limits of the study

The design of this analysis is retrospective, and it was conducted in a single oncology institute. The number of patients included in the study was quite small (90 patients) and several types of analysis were performed irrespective of the patient's stage. We were not able to confirm several of the well-known prognosis factors for melanoma.

CONCLUSIONS

In our study, red cell distribution width is a promising new prognosis factor for patients with malignant melanoma. Alongside other parameters already in use, regularly assessing it can improve survival predictions and aid physicians working with cancer patients in decision-making and communicating with the family. Additional studies, preferably with a prospective design, are required to certify our analysis' findings.

IS THERE A CARDIOVASCULAR RISK IN INFLAMMATORY BOWEL DISEASES? (Abstract): Inflammatory bowel diseases (IBD) are characterized by an increased thrombembolic risk, given the powerful relation between inflammation and thrombosis. Multiple studies showed that patients with IBD have an up to 3-fold higher risk for developing venous thrombembolic (VTE) complications compared to general population, this risk being more increased in the hospitalized IBD flares. Thus, latest consensus recommendations indicate prophylaxis for VTE in hospitalized patients with active IBD but with no clear indications for the management of IBD outpatients. Regarding atherothrombotic risk (myocardial infarction or stroke), up-to-date data are inconclusive. IBD is associated with subclinical atherosclerosis in patients without clinical manifestations of cardiovascular diseases (CVD). However, the results of major studies assessing the hypothesis that IBD is strongly associated with atherosclerotic macrovascular events prove to be divergent even if they show positive correlations with CVD especially on different subgroup analysis. These facts should lead in the future to more prospective studies with control groups that have the same cardiovascular risk profile as in IBD populations in order to admit definitively that patients with IBD are exposed to an increased cardiovascular risk. **Keywords**: INFLAMMATORY BOWEL DISEASES, CARDIOVASCULAR RISK, VENOUS THROMBEMBOLISM, MYOCARDIAL INFARCTION, STROKE

Cardiovascular diseases (CVD) still represent the main cause of mortality worldwide despite the implementation of major programs of primary prevention. More than 70% of total deaths caused by CVD are determined by complications of atherosclerosis (about 50% - coronary disease, 20% - stroke).

Atherosclerosis represents a chronic inflammatory disease which is characterized by general inflammation. The immune mechanisms, in combination with well known metabolic risk factors (e.g. hypercholesterolemia, smoking), are key components in the initiation, activation, propagation and complication of the atherosclerotic plaque that, by rupture and thrombosis, will finally lead to acute coronary syndromes, strokes or other acute manifestations (1). In the last years, there is a growing interest in the involvement of the inflammatory and immune actions in the process of athero-

genesis that will lead in the future to a translational medicine from the pathogenesis to clinical approaches of atherosclerosis. More biomarkers promise to play a great role in detecting subclinical activity, such as high-sensitivity C reactive protein (hs-CRP), cytokines (IL-6), proteases such as matrix metalloproteinase 9 or myeloperoxidase (2). The major problem is that in more than 30% of cases, the first clinical manifestation of atherosclerotic burden is a myocardial infarction. This is due to the fact that the disease acts undetected or the patient is wrong classified into a lower risk class with an inappropriate treatment and weak prevention measures.

Taking into consideration the upmentioned facts, it is with no doubt and it is well proved that chronic inflammatory diseases, such as systemic lupus erythematosus, rheumatoid arthritis or psoriasis, are associated with an increased cardiovascular risk. Regarding inflammatory bowel diseases (IBD), the relationship with atherothrombotic cardiovascular events is quite unclear, even if certain studies tend to suggest that there is a direct connection between these two diseases. Thus, our aim is to provide a concise overview over the current and latest studies regarding the relationship between inflammatory bowel diseases and the associated cardiovascular risk.

IBD include two main entities: Crohn's disease and ulcerative colitis, with an estimated prevalence of 2.2 million persons in Europe. Even if it is long studied, the precise pathological mechanisms that lead to the development of the diseases are not fully understood. Certain contributing factors are represented by cigarette smoking, family history of IBD and appendectomy (3).

However, given the inflammatory status in IBD, these patients possess a greater thrombembolic risk, the link between thrombosis and inflammation being well recognized. This may be due to different mechanisms such as microvascular injury, a state of hypercoagulability, increased platelet activation or higher incidence of hyperhomocysteinemia in IBD patients (4, 5).

Moreover, in patients without clinical manifestations of CVD, IBD is associated with subclinical atherosclerosis, with increased carotid intima media thickness, arterial stiffness, hs-CRP, homeostasis model assessment of insulin resistance (HOMA-IR) or atherogenic lipid profile, suggesting higher risk of atherothrombotic disease (6).

There is a general agreement that patients with IBD have an increased risk of thrombembolic manifestations with the predominance of venous rather than arterial complications.

Multiple metaanalysis have proven that patients with IBD have an up to 3-fold higher risk for developing venous thrombembolic (VTE) complications compared to general population, this risk being even more increased in the hospitalized IBD patients (7, 8).

In a large case-control study involving almost 100,000 cases, Grainge et al. prove that patients with IBD had higher risks of VTE events, with an up to 8-fold higher risk during the IBD flares (9). In IBD inpatients, the prevalence of venous thromembolism is 32% increased in patients with Crohn's disease than in those with ulcerative colitis, but overall two times higher than in subjects without IBD. This fact leads finally to higher treatment charges and mortality in IBD patients that associate thrombotic complications (10). Another multicenter study concludes that patients

with IBD and venous thrombembolism are more prone to develop recurrent venous thrombembolism. But the same study states that it is uncertain which patients would benefit from prolonged therapy with anticoagulant, taking into the balance both the risk of bleeding and the risk of recurrent thrombotic complications (11).

However, current consensus recommendations indicate prophylaxis for venous thrombembolism in hospitalized patients with active IBD. Thrombophylaxis proves to be safe in patients with IBD even during a flare when there is rectal bleeding. Despite this evidence, up to two thirds of gastroenterologists do not administer venous thrombembolism prophylaxis to patients hospitalized with acute colitis. There is a great unevenness among physicians regarding the necessity, the way the VTE prophylaxis should be performed and the long term follow of such cardiovascular complications (12). Future clinical trials are needed to confirm safety and effectiveness of venous thrombembolism prophylaxis in outpatients with active disease (13). This last statement is underlined by other recently published studies which confirm that approximately half of thrombembolic events in IBD patients occur after hospital discharge, especially in those with additional risk factors for VTE (e.g. after a hospitalization for an IBD flare or after surgery) (14, 15). Moreover, IBD subjects present in the first 30 days after surgery a double risk for developing deep vein thrombosis or pulmonary embolism compared to general population, but without higher additional risk for myocardial infarction or stroke (16).

Taking into account these considerations, in 2014 is released the Canadian Association of Gastroenterology guidelines regarding treatment and prophylaxis of venous thrombembolism in patients with IBD which makes the following main recommendations based on current evidence (17). For:

- hospitalized IBD patients with moderate-severe IBD flares without severe bleeding, it is recommended anticoagulant thromboprophylaxis with low molecular weight heparin, low-dose unfractionated heparin or fondaparinux;
- IBD patients, even in clinical remission, hospitalized for other medical indications unrelated to IBD, it is recommended anticoagulant thromboprophylaxis;
- IBD patients that underwent major general or abdominal-pelvic surgery, it is recommended anticoagulant thromboprophylaxis during hospitalization;
- outpatients with IBD flare who did not experience a previous venous thrombembolism, it is NOT recommended anticoagulant thromboprophylaxis;
- IBD outpatients with a previous venous thrombembolism and are no longer on anticoagulation, it is recommended anticoagulant thromboprophylaxis during moderate-severe IBD flares;
- IBD patients who undergo their first venous thrombembolism episode, even with IBD in clinical remission and in the absence of other provoking factor, it is recommended indefinite anticoagulant therapy with periodic reassessment of this indication;
- IBD patients with active disease, diagnosed with their first venous thrombembolism episode, it is recommended anticoagulant therapy at least until the IBD is in remission for 3 months or indefinite anticoagulant therapy.

Thereby, until new evidence regarding

anticoagulant treatment in IBD outpatients are released, an initial pragmatic approach is preferred in order to decrease the thrombembolic risk in IBD outpatients. This approach is represented, firstly, by an appropriate education of the patients for reducing and preventing thrombotic risk factors, recognizing early signs and symptoms of the venous thrombotic events and a regular clinical evaluation of the patients made by the specialist for the evaluation of possible venous complications (18).

While venous thrombembolic events have a higher incidence in subjects with IBD, the debate persists if IBD also correlates with atherotrombotic diseases including myocardial infarction or stroke.

A meta-analysis published in 2007, comprising 11 studies with more than 14000 participants concluded that IBD were not associated with increased CV mortality (19). In addition to this, Osterman at al. (20) conducted two retrospective cohort studies, with more than 25,000 patients with IBD with a mean follow-up of 4.5 years and found that neither Crohn's disease nor ulcerative colitis had an increased risk of myocardial infarction. Another case-control study made by Ha et al. (21) supported once again the idea that these patients did not have an overall increased risk of arterial thrombotic events even if some subgroup analysis revealed some positive correlations (e.g. women below 40 years had a two-fold higher risk for stroke).

Nevertheless, there are studies that show direct causal link between IBD and further CV events. Bernstein et al. (22) concluded on more than 8,000 IBD patients that these subjects were more likely to develop cardiac atherosclerotic events, regardless of sex, with a 32% higher incidence of stroke in patients with Crohn's disease. Moreover, in a cohort that included more than 8000 persons with Crohn's disease, only the subgroup with younger patients (aged less than 50 years) presented a 3-fold increased risk of stroke but with no increased risk in older patients (23). Yarur et al. (24) proved in another 4-year cohort study that patients with IBD had a higher risk of coronary artery disease (hazard ratio 2.85) despite associating a lower burden of cardiovascular risk factors.

Probably the most important study that supports a direct causal link between CVD and IBD is the Danish Nationwide Cohort Study conducted by Kristensen (25) which included more than 20,000 patients with IBD matched for age and gender with 200,000 controls. The study concluded that there was an increased risk of myocardial infarction, stroke and CV death in patients with IBD but only during episodes of flare or periods of persistent active disease, whereas the risk was the same as in the control population in patients with IBD remission. However, this study did not take into consideration other cardiovascular risk factors or different treatments that the subjects could have followed at that time. One recently published evidence is offered by Singh et al. (26) in a systematic review over 9 studies. The authors found a slightly increased risk of stroke and ischemic heart disease in patients with IBD, especially in women, but with no difference for peripheral artery disease. The CVD risk was similar both for Crohn's disease and for ulcerative colitis patients.

It is certain that IBD subjects are predisposed to an accelerated atherosclerosis process mostly secondary to chronic general inflammation. But with all the upmentioned inconsistent results, it is clear

there is a great heterogeneity in the population with IBD and with different degree of endothelial injury that finally leads to different CV risk. However, there are some categories that can be included into a higher risk, such as patients with extensive bowel involvement, longer activity or severe persistent disease (27).

In summary, IBD proves to be associated with an up to 3-fold increased risk of developing venous thrombembolic events. This leads to firm indication for anticoagulant thromboprophylaxis for IBD hospitalized patients. Regarding the atherothrombotic risk, there is good evidence that IBD have relevant subclinical atherosclerotic lesions. However, studies are divergent in concluding that IBD are strongly associated with macrovascular events, such as myocardial infarction or stroke, even if they prove positive correlations with CVD especially on subgroup analysis. There are needed more prospective studies with control groups that have the same cardiovascular risk profile as in IBD populations in order to conclude definitively that patients with IBD have an increased risk for developing CVD.

INFLUENCE OF MONTELUKAST ON CISPLATIN-INDUCED EXPERIMENTAL ACUTE RENAL FAILURE (Abstract): **Aim:** To investigate the influence of Montelukast (MK) in acute renal failure (ARF) experimentally induced by cisplatin (CIS). **Material and methods**: The experiment was carried out in male Wistar rats (280-320g), divided into 4 groups of 12 animals each, treated as follows: Group I (Control); Group II (CIS): CIS, 5 mg/kbw, single dose, i.p.; Group III (CISMK): CIS, 5 mg/kbw, single dose, i.p and MK 2mg/kbw, p.o., 10 days; Group IV (MK): MK 2mg/kbw, p.o., 10 days. Blood and urine (24 h) samples were taken before the start of experiment (Io) and at 3, 7, 10 and 14 days after CIS administration. The following were determined: urea, creatinine, Ca, Mg serum levels and creatinine, proteins, Ca and Mg urinary levels. For histological evaluation, 3 rats of each group were sacrificed at 3, 7, 10 and 14 days. The severity of histopathological changes was evaluated using scores on a 1-4 point scale. **Results:** Both in CIS and CISMK group, serum levels of urea and creatinine and urinary protein levels were significantly higher compared with Io values and control group at 3 and 7 days, ($p<0.01$ and $p<0.05$, respectively). Urinary creatinine levels were significantly decreased at 3 and 7 days, ($p<0.01$) and ($p<0.05$) in CIS and CISMK group compared to Io and control group. The degree of severity of histopathological changes was similar in CIS and CISMK group. **Conclusions:** The obtained results showed that MK at a dose of 2mg/kbw had no protective effect in CIS-induced experimental acute renal failure. **Keywords**: CISPLATIN, MONTELUKAST, ACUTE RENAL FAILURE.

Cisplatin (cis-diamminedichloroplatinium II, (CDDP) (CIS) is an anti-neoplasic drug used in the treatment of solid tumors, such as brain, neck, lung, testicular or ovarian tumors. The main side effect which limits the use of cisplatin is its nephrotoxicity. One of the most common renal manifestations caused by cisplatin treatment is acute kidney injury. The kidney accumulates cisplatin more than other organs, the concentration of cisplatin in the epithelial cells of the proximal tube being 5 fold higher than the serum concentration (1). Cisplatin accumulates in the renal cells by active transport and passive diffusion through the cellular membrane. Transporter-mediated accumulation of cisplatin is the major intake mechanism in renal cells. Recent studies have identified 2 different membrane transporters capable of transporting cisplatin into cells: Ctr1 and OCT2. Ctr1 is a cooper transporter which also seems to

mediate cisplatin uptake; Ctr1 is found in a significant concentration in the kidney and localizes to the basolateral membrane of the proximal tube. OCT2 is an organic cationic transporter and is found predominantly in the kidney; recent studies showed that the deletion of OCT2 gene significantly reduces the urinary excretion of cisplatin and nephrotoxicity (2).

Montelukast (MK) is a selective cysteinyl leukotriene receptor 1 (CysLT1) antagonist used in the treatment of asthma. MK is an anti-inflammatory drug with antioxidant properties that interferes directly with leukotriene receptors. Some recent studies highlight that Mk is a highly free radical scavenger, balancing oxidant-antioxidant status and regulating the generation of inflammatory mediators (3).

In this study we investigated the influence of MK in CIS-induced experimental acute renal failure in rats.

MATERIAL AND METHODS

Sinplatin (cisplatin), 1mg/ml concentrate for solution for infusion (SINDAN PHARMA SRL, ROMANIA) and Montelukast film-coated tablets, 10 mg, (TEVA) were used.

Adult male Wistar rats (280-320g) were used in the study. The animals were housed in a temperature (22-24^{0}C) controlled room with a constant 12 h light/dark cycle, in plastic cages with free access to standard food and water. After a quarantine period, the animals were divided into 4 groups of 12 subjects each, housed in standard metabolic cages and treated as follows Group: I (Control); II (CIS): CIS, 5 mg/kbw, single dose, i.p.; group III (CISMK): CIS, 5 mg/kbw, single dose, i.p and MK 2mg/kbw, by gastric gavage, 10 days; group IV (MK): MK 2mg/kbw, by gastric gavage, 10 days.

Blood samples from the retro-orbital plexus were taken before the start of the experiment (Io) and at 3, 7, 10 and 14 days after the CIS administration. 24-hour urine samples were collected from all animals in individual metabolic cages, at the same time periods as blood samples. The urinary volume was measured. Serum levels of urea, creatinine, Ca, Mg and urinary levels of creatinine, proteins, Ca and Mg were determined. For histological evaluation, 3 rats of each group were sacrificed at 3, 7, 10 and 14 days under ether anesthesia and the kidney samples were taken. All biochemical parameters were determined using RANDOX diagnostic kits on Rx Daytona analyzer.

A semi-quantitative assessment of renal tissues was realized using a scale for the degree of injury severity in agreement with the criteria for laboratory methods. The scores for the severity of changes were measured on a scale from 1 to 4 as follows: (1) minimal (affecting < 25%); (2) mild (affecting 25-50%); (3) moderate (affecting 50-75%) and (4) severe (affecting > 75%). All kidney sections were evaluated for degeneration/necrosis of the proximal tubules (PT), distal tubules (DT), collector duct (CD) (with or without regeneration), intratubular casts, hyaline, cortex and interstitial inflammation. Two whole organ sections were examined and an average score was obtained.

The use of animals and the experimental protocol were in agreement with the "Grigore T. Popa" University of Medicine and Pharmacy guidelines for Research and Ethical Issue and also in compliance with the ethical standards of the European Community.

The results were statistically evaluated by one-way analysis of variance (ANOVA) and t-test. p-values <0.05 were considered statistically significant. All data are pre-

sented as mean±standard deviation (SD).

RESULTS

During the experiment the animals did not show significant signs of toxicity. The animals receiving CIS and CISMK showed weight loss (10%) in comparison with the MK and control groups. The 24h-urine volume in CIS and CISMK groups decreased significantly ($p < 0.05$) at 3 and 7 days compared to baseline values (Io) and increased significantly ($p<0.05$) at 14 days (tab. I). Serum urea and creatinine levels were significantly higher in CIS and CISMK groups at 3 and 7 days, ($p<0.01$ and $p<0.05$, respectively), compared to Io values and control group (tab. II). Mg serum levels significantly increased at 3 days, ($p<0.01$) in CIS and CISMK groups, compared to Io and control group (tab. III).

TABLE I

Urine volume (24h) in CIS, CISMK, MK and control groups (X±SD)

Parameter	Group	Io	3 days	7 days	10 days	14 days
24-h urine volume (ml)	CIS	24.71±9.06	14.85±6.49 *p<0.05	13.0±2.0 **p<0.01	30.66±5.77	34.00±4.5 *p<0.05

*p<0.05; **p<0.01 compared with Io

Urinary proteins increased significantly at 3 and 7 days, ($p<0.01$), ($p<0.05$) in the groups receiving CIS and CISMK, in comparison with Io values and control group. Urinary creatinine was significantly lower at 3 and 7 days in CIS and CISMK groups, ($p<0.01$ and $p<0.05$, respectively), compared to Io (tab. IV).

Urinary Mg and Ca levels were significantly lower at 3 days (p<0.001) in CIS and CISMK groups, compared with Io and control group. At 7 days, urinary Ca and Mg levels registered a significant increase (p<0.01), in comparison with the 3 day levels (tab. V). No significant differences in biochemical parameters between CIS and CISMK were detected.

The histopathological examination showed no differences between controls and MK group. In CIS and CISMK groups, degenerations and tubular necrosis of mild to moderate severity at 3 and 7 days were found. At 10 and 14 days the injury severity was 1 and 2. Cisplatin induced degeneration/ necrosis of the S3 segment of the renal proximal tubules. Tubular dilations of

the renal cortex of mild severity were also noticed in all animals. Also, mild regeneration was associated with degeneration/ necrosis.

DISCUSSION

Conversion of cisplatin to toxic compounds takes place in the proximal tubular cells (4). On experimental models, cisplatin affects the proximal tubular cells of the internal renal cortex and outer medulla (S3 segment), the most damaged region by cisplatin. Depending on the dose, it can also damage the distal tubule and collecting duct. Morphological glomerular changes are not present (5, 6). 72 hours after cisplatin administration proximal and distal tubular reabsorption is impaired and vascular resistance is increased. The proximal tubule loses the epithelium responsible for favoring the flow of substances into its cells. This process involves the formation of concentrated urine, which leads to increased levels of toxic compounds in the tubular fluid.

Our results showed a good correlation, individually, between the presence of mild to moderate degeneration/necrosis at 3 and 7 days, higher serum urea and creatinine levels, higher urinary protein levels and lower urinary volume. The 2mg/kbw MK dose had no protective effect in acute renal failure induced by CIS.

ARF is associated with renal vasoconstriction, reduced GFR, decreased urine output and increased serum creatinine. Creatinine is secreted through organic cation pathway located in the basolateral side of the proximale tubules. The proportion of tubular creatinine secretion increases with worsening renal function, while urine creatinine excretion decreases and extra-renal secretion of creatinine increases. Serum creatinine can therefore overestimate GFR in advanced renal dysfunction (7).

MK is a well known anti-asthmatic drug, which also has other pharmaco-dynamic effects (8). There are data that show that the CysLT1 antagonist has an anti-ulcer activity (9, 10), as well as a protective effect in burn-induced oxidative injury of the skin (11). Some other studies suggest that MK has a

partially protective activity in experimental intoxication with carbon tetrachloride (12). There are studies that show that the CysLT1 antagonist at a higher dose than we used in our experiment had a positive effect in acute renal failure experimentally induced by cisplatin, gentamicine, amykacine (13, 14).

CONCLUSIONS

The results obtained in our study show a good correlation between the biochemical parameters that define ARF and the histopathological changes found, and demonstrate that CIS, 5 mg/kbw, i.p., induced an abrupt (within 48 h) reduction of kidney function in rats.

MK dose of 2 mg/kbw used in our experiment did not have a protective effect in CIS-induced experimental acute renal failure.

THYROID FUNCTION DURING THE FIRST YEAR OF RECOMBINANT HUMAN GROWTH HORMONE THERAPY IN SHORT STATURE CHILDREN (abstract) **Introduction:** The relationship between rhGH treatment and thyroid function has been the subject of numerous studies. Some say that rhGH treatment unmasks central hypothyroidism, other say that rhGH induces subclinical primary hypothyroidism. **Aim:** To assess the changes in thyroid function in short stature children in the first year of treatment with rhGH and the impact on growth velocity. **Material and methods**: We evaluated 37 patients treated with rhGH, 5 were excluded because developed side effects during treatment. We measured height, height velocity, and height standard deviation gain during treatment and thyroid function during the first year of treatment. **Results**: We observed a slight increase in the TSH level and no significant change in the f T_4 level after the first 3-6 months of treatment in all the groups; in GH deficiency (GHD) patients, we observed a statistically significant decrease of the f T_4 level after the first 3-6 months, without a significant increase of the TSH level. After the first year, thyroid function returned to baseline. There were no differences between height velocities in all the groups, except from the GHD patients. **Conclusions**: The slight increase in the TSH level and the decrease of f T_4 level might unmask a transient subclinical primary hypothyroidism but these changes do not influence the growth velocity in first year of rhGH treatment. **Keywords**: RECOMBINANT HUMAN GROWTH HORMONE (rhGH), THYROID FUNCTION, TSH, FT_4

Recombinant human growth hormone (rhGH) has been approved for the treatment of growth deficiency (GHD) in both children and adults since 1986 and also since then, the indications have been extended to other non-GH deficient diseases in children, such as idiopathic short stature, Turner syndrome, small for gestational age, Prader–Willi syndrome. rhGH can be given as a replacement dose (for GHD) or pharmacologic (for most other conditions).

In children with GHD, rhGH treatment is given in doses that reproduce the daily normal secretion of growth hormone. In pharmacological dose, rhGH stimulates growth-promoting pathways affected by the diseases or not functioning properly (1). In these cases rhGH is used in higher doses in order to overcome the relative GH or IGF-1 insensitivity. The response to treatment depends

on the sensitivity to GH, the dosage and the age of initiation of the treatment (2).

The relationship between rhGH and hypothalamus-pituitary-thyroid axis has been the subject of several studies with divergent results. Researchers showed that rhGH treatment induces a fall in serum total and free T_4 concentration, an increase in serum T_3 concentration, independent of the TSH action, which decreases or remains unchanged. Several explanations have been issued for these effects but most of them are contradictory (3-8).

The aim of our study was to evaluate the changes induced by the rhGH treatment on the thyroid function and the impact on velocity in short stature children in the first year of treatment with rhGH.

MATERIAL AND METHODS

We evaluated children treated with rhGH between 2009 and 2012, in our Department of Endocrinology. Patients were included in our study based on the inclusion criteria for rhGH treatment of the current national recommendations in the program of therapy of short stature children (9). Parental informed consent was obtained from all the participants in our study.

The retrospective analysis included 37 patients. We divided our patients in 4 subgroups: growth hormone deficient (GHD) 17 patients, Turner syndrome 4 patients, small for gestational age (SGA) 5 patients and idiopathic short stature (ISS) 6 patients (tab. I).

TABLE I

*groups compared to one another, with statistical significant difference ($p<0.05$)

Patient height was obtained by direct measurement on a wall mounted stadiometer and standard deviation was assessed using Prader 1989 growth charts. Target height was calculated using the formula: (father's height+mother's height ± 13 cm)/2. Bone age was calculated according to Greulich-Pyle's 1959 standards (10) or Tanner Whitehouse 20 system. All the stimulation tests and blood samples were

performed during the morning hours.

Diagnosis of GHD was based on height below - 2.5 standard deviations (SD), bone age delayed with more than 2 years, low or normal IGF-1 for age and sex and at least 1 negative stimulation test for growth hormone. We performed clonidine stimulation test with 0.15 mg/m^2 or insulin tolerance test with 0.15 IU/kg. GHD was established if GH peak was less than 10 ng/ml. Severe GHD was assessed as peak GH less than 3 ng/ml.

Diagnosis of SGA was based on birth weight less than -2 SD or length less than – 2 SD compared to normal values for gestational age, height below – 2.5 SD at the age of 4.

ISS was diagnosed in the presence of a height less than - 3 SD, with normal nutritional status, no history of chronic diseases and after having excluded any other cause of growth failure.

Diagnosis of Turner syndrome was made on the clinical phenotype and confirmation by karyotyping of peripheral blood leukocytes. Diagnosis for Noonan syndrome was made clinically and Prader-Willi syndrome was diagnosed based on methilation analysis.

We excluded children less than 3 years of age and we did not start treatment until we excluded other possible secondary causes for growth failure like decompensated cardiac abnormalities, decompensated renal failure, malabsorption, congenital hypothyroidism, Cushing syndrome, decompensated diabetes mellitus, skeletal deformations, vitamin D deficiency, pituitary tumors, active malignant tumors or genetic disorders other than Turner syndrome, Noonan syndrome, Prader-Willi syndrome or Russel Silver (approved in our country for rhGH therapy).

Clinical aspects. The patients have been regularly followed up at our clinic.Before starting rhGH treatment; we assessed all the antropometric parameters, like birth height and weight, actual length and weight, target height, bone age and signs of puberty. We also obtained magnetic resonance images of the sellar region in order to exclude possible intracranial tumors. MRI showed partial empty sella in one girl with Turner syndrome, complete empty sella in one SGA boy, agenesis of corpus callosum in a GHD girl and pituitary hypoplasia in 2 children with GHD.

During each visit at 3, 6, 9 and 12 months after initiation of rhGH therapy, patients were closely checked for body height, weight, bone age, signs of pubertal development, complete blood count, fasting glucose levels and thyroid function – TSH, fT_4 and thyroid antibodies in case of hypothyroidism.

Treatment. Thyroid function was normal in most of the children (24 cases) but in the remaining 8 cases, 3 in GHD group, 3 in Turner group, one in SGA group and one in ISS group, levothyroxine was administered for primary hypothyroidism in order to maintain TSH and fT_4 values within the normal range and the dose was adjusted at each visit during follow-up. Three children had positive thyroid anti peroxidase antibodies.

All the patients except one girl were prepubertal at the time of diagnosis and no priming was necessary. The girl had Turner syndrome and conjugated estrogen therapy was started one year before initiation of rhGH therapy. Bone age was delayed in all groups with the exception of Turner patients with a bone age similar to the chronological one.

The dose of rhGH was adjusted in order to maintain an IGF-1 level within the normal range for sex and age.

Plasma TSH and fT_4 concentrations

were measured using an electrochemiluminescence immunoassay „ECLIA". Growth hormone concentrations were measured by IMMULITE® 2000 Growth Hormone. IGF-1 was assessed by an automated chemiluminescent assay system (IMMULITE®, Diagnostic Products Corp., Los Angeles, CA, USA) and the normal range was corrected for age.

Statistical analysis was performed in GraphPad prism 6, Demo Version. Numerical data are expressed as mean ± SD. We used *t*-test for paired data, Wilcoxon's test for non-parametric data with non-Gaussian distribution. When we analyzed the differences between more than three groups, we used ANOVA test. The level of statistical significance was at $p < 0.05$.

RESULTS

During follow up, we excluded 5 patients: one girl developed type 1 diabetes mellitus 8 months after rhGH treatment, one boy developed restrictive cardiomyopathy after 4 years of treatment, one boy presented high glucose levels 1 year after treatment, one girl with Prader-Willi syndrome presented aggravated obstructive sleep apnea 3 months after starting rhGH treatment and one boy was lost during follow-up. No other serious side effects were reported, except for a suspicion of epiphisiolysis in 14 years old, unconfirmed by the orthopedics.

We observed a slight increase without statistical significance in the TSH level and no significant change in the fT_4 level after 3, 6, 9 or 12 months of treatment in all the groups (tab. I, fig. 1A, B). The increase of the TSH level was highest after the first 3-6 months of treatment and during the first year it returned to pretreatment levels. The small changes of fT_4 level also stabilized after the first year of rhGH treatment (fig. 1C).

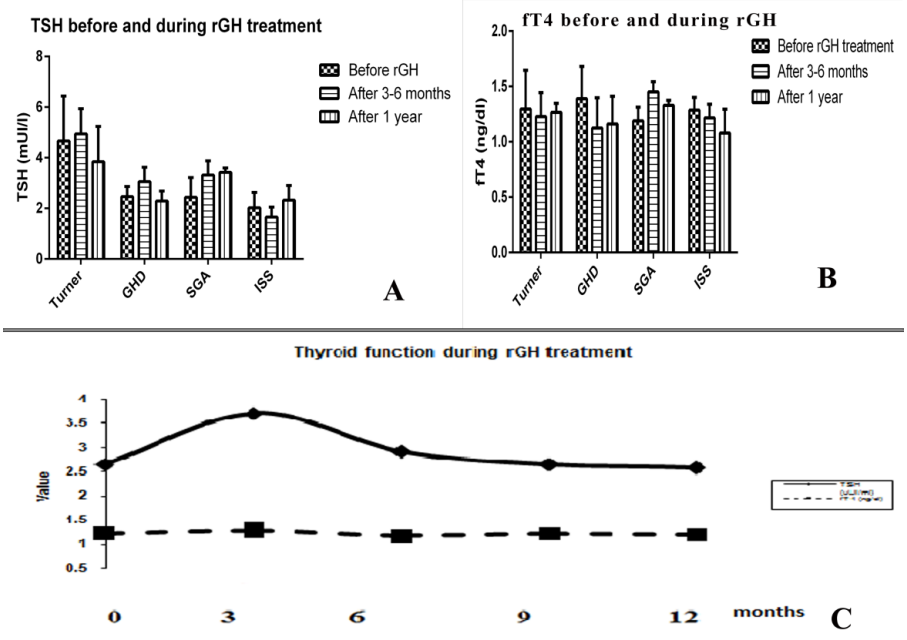

Fig. 1. Thyroid function evolution during the first year of rhGH treatment.

We compared TSH values between the 4 groups at the same time during monitoring. We observed a statistically significant difference of TSH values at 3-6 months only between Turner patients and ISS patients (tab. I).

Despite these changes, none of the patients from the euthyroid group needed levothyroxine supplementation as compared to four of the patients previously treated with levothyroxine who needed a small increase of the dose with an average of 25μg/day in order to maintain TSH values within the normal range.

In a subgroup analysis for GHD patients, changes of the thyroid function were more evident, with a significant fall in serum fT_4 levels after 3 and 6 months of rhGH therapy (fig. 2B). fT_4 was towards the lower limit but always within the normal range and we decided not to start levothyroxine substitution therapy. We did not find a significantly increase in the TSH level after the first months of treatment (fig. 2A) as we would have expected based on the fall of fT_4 levels.

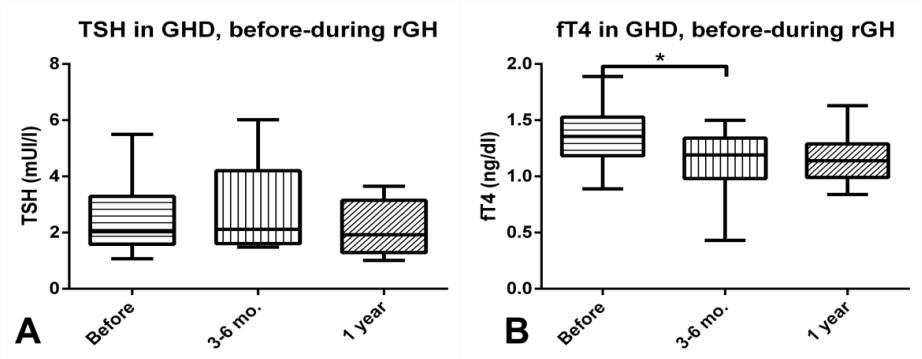

Fig. 2. Thyroid function in the GHD patients during the first year of rhGH treatment.

There were no statistical differences between height velocities and height standard deviation gain in the first year of rhGH treatment in all groups (tab. 1, fig. 3).

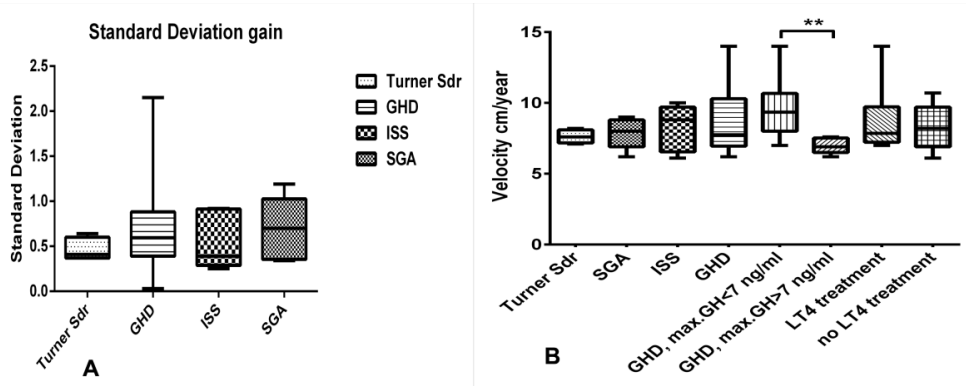

Fig. 3. Height velocity during the first year of rhGH treatment

The greatest height velocity was observed in the GHD group while height standard deviation gain was the most important in SGA group. The lowest gain was seen in Turner group. We did not notice any differences regarding velocity and height standard deviation gain between the euthyroid patients and those with previous levothyroxine substitution before rhGH therapy. In the GHD subgroup we observed a statistical difference in the height velocity between those who had a maximum GH during clonidine stimulation test less than 7 ng/ml versus those with maximum GH more than 7 ng/ml (fig. 3B).

DISCUSSION

This study demonstrates that during rhGH therapy for short stature children, thyroid function is influenced by a shift of fT_4 levels toward the lower limit and slightly elevated levels of TSH in all euthyroid children. The same changes were also seen in the patients with previous primary hypothyroidism but adequately substituted with levothyroxine.

Based on the results of our study, we issued several hypotheses. One of them is that rhGH treatment induces an increase in the activity of deiodinase type I and III which leads to increased peripheral conversion of T_4 to T_3. The increased levels of T_3 might lead to decreased secretion of TSH through negative feedback. Also, the decreased levels of f T_4 induce through negative feedback an increased secretion of TSH. Together, these might explain why TSH level remains relatively low as compared to the decreased level of f T_4, such as seen in central hypothyroidism. Of great interest would be to determine the effect of rhGH treatment on the TRH gene expression in the hypophysiotropic neurons and the activity of type 2 deiodinase (D II), the primary thyroid hormone activating enzyme in the mediobasal hypothalamus and also in peripheral tissues. Another hypothesis of ours is that rhGH induces inhibition of TRH gene expression by increasing the local thyroid hormone activation in the hypothalamus and leading to central subclinical hypothyroidism. In addition, we hypothesize that an increase of DII activity in peripheral tissues may also contribute to the altered peripheral T_3/ T_4 ratio.

Previous studies have shown that rhGH therapy might unmask a central hypothyroidism in the face of low fT_4 with inadequately elevated TSH levels (5). Others contest this explanation by showing that fT_4 changes induced by rhGH therapy are independent of TSH secretion and are caused by the increased peripheral conversion of T_4 to T_3 which will determine a blunt TSH secretion via negative feedback (6). Because of these effects on thyroid hormones, Portes et al suggest that serum T_3 levels have no use in the diagnosis of central hypothyroidism but they would be useful to indicate excessive thyroxine supplementation (6).

Since we could not measure the T_3 serum concentration to justify the physiological response of TSH secretion, we interpret the changes seen in our patients as a transient subclinical central hypothyroidism which resumed after the first year of rhGH therapy. A same hypothesis issued Seminara et al (7).

Despite these changes in the thyroid function, we did not start levothyroxine substitution in our previous euthyroid patients because none of the values of fT_4 were below the normal limit and none of our patients developed signs or symptoms suspicious of hypothyroidism. We in-

creased the dose of L- T_4 in only four patients with previous primary hypothyroidism because of increased TSH levels above the normal limit, especially in the group of patients with Turner syndrome. As it has been shown, children with Turner syndrome are predisposed to thyroid disorders, especially hypothyroidism induced by thyroid autoimmunity, leading to increased levels of TSH and low or normal levels of fT_4 (11). This mechanism also explains the significant statistical difference we observed when comparing the TSH value at 3-6 months between Turner patients and ISS patients.

When comparing fT_4 levels we observed a statistical difference between the lower fT_4 values in GHD patients compared to fT_4 levels in SGA patients. We explain this difference as a direct effect of rhGH supplementation in GHD patients and increased peripheral conversion of fT_4 to T_3, as compared to SGA patients.

We assume that the transient changes in TSH and fT_4 are a consequence of a new equilibrium established once rhGH therapy has been started, especially in those with growth hormone deficiency. The transient changes of thyroid function seen in our study were also reported by other researchers but the mechanisms remain unclear. Besides the increased peripheral conversion of fT_4 to T_3 through stimulation of deiodinase type I and III, and decreased conversion of T_4 to r T_3 (8), some say that the extracellular water increase might determine these shifts in thyroid hormone levels (12). Another possible explanation for the lack of significant changes in TSH level is the increased somatostatinergic tone through somatostatin, the natural inhitor of TSH during rhGH therapy (13).

Despite these changes, we did not notice any negative impact on growth velocity and height standard deviation gain in either of the studied groups. The positive growth response might be explained by the increased levels of serum T_3 actively acting in periphery. All patients had velocities expected for the treatment schedule. There were no changes in velocity when comparing euthyroid patients to those with levothyroxine substitution before the onset of rhGH therapy which further supports our hypothesis that these changes in the thyroid function are transient and there is no need for levothyroxine substitution unless there are clear changes suggestive for hypothyroidism, especially in those patients previously known with thyroid diseases.

CONCLUSIONS

During the first year of rhGH treatment, there are changes in the thyroid function, with a slight increase in the THS level and a decrease of fT_4 level. We suppose that these changes unmask a subclinical primary hypothyroidism but do not influence the growth velocity. There should be a careful decision for supplementation with levothyroxine in previous euthyroid children, since the changes in thyroid function are transient and return to baseline values within one year of continuous treatment with rhGH. Further studies are necessary in order to establish the effects of rhGH treatment at the hypothalamic and pituitary level and the impact on thyroid hormone metabolism.

ANXIETY AND DEPRESSION IN PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE: AN OPEN AGENDA FOR RESEARCH (Abstract): Depression and anxiety are psychiatric conditions often associated with poor survival rate and impaired social functioning in chronic illnesses, like chronic obstructive pulmonary disease (COPD). COPD is a major cause of chronic morbidity and mortality, being nowadays the fourth leading cause of mortality worldwide and the burden of this disease is increasing as the population is ageing and it is continuously exposed to risk factors. Common mechanisms for explaining the association of anxiety, depression and COPD include cigarette smoke exposure, physical inactivity, social isolation, multiple episodes of dyspnea and chronic hypoxia. BODE index and MMRC dyspnea score could be associated with anxiety and depression in COPD patients and the screening usually implies administration of simple questionnaires. Therapeutic options for anxiety include serotonin-reuptake inhibitors, which decrease the perception of dyspnea, while newer antidepressants, such as venlafaxine, duloxetine and mirtazapine are particularly useful in depression, since they do not produce respiratory depression. **Keywords**: CHRONIC OBSTRUCTIVE PULMONARY DISEASE, DEPRESSION, ANXIETY.

Depression and anxiety are psychiatric conditions that cause significant social disability being characterized by sleep disturbances, weight cycling, depressed mood, loss of interest in nearly all activities, and somatic symptoms of tension (psychomotor agitation, dyspnea, irregular heartbeats) (1, 2, 3). In chronic illnesses, depression is often associated with poor survival rate and impaired social functioning (1).

Chronic obstructive pulmonary disease (COPD) is a major cause of chronic morbidity and mortality, being nowadays the

fourth leading cause of mortality worldwide. COPD burden is increasing as the population is ageing and it is continuously exposed to risk factors such as smoking, occupational or environmental exposures to various particles (4).

Patients with this progressive respiratory disease often experience physical and role limitations, expressed as anger, frustration, physical and emotional dependency, and consequently guilt and embarrassment (5).

Anxiety and depression are considered major co morbidities in COPD, both associated with poorer prognosis, and a large number of studies provided relevant information (6).

THE IMPACT OF ANXIETY AND DEPRESSION IN COPD PATIENTS

The prevalence of generalized anxiety disorder in COPD patients is considered to be raging between 10% - 33%, with a prevalence of panic attacks up to 67% (7, 8). A small study comparing 20 subjects with COPD with a control group of 20 patients hospitalized for degenerative orthopedic conditions revealed that anxiety disorders among respiratory patients had a prevalence of 55%, compared with 30% in the orthopedic group and among anxiety disorder panic disorder was the most prevalent expression of psychiatric disease (9).

On the other hand, the prevalence of major depressive disorder in the same patients ranges between 37% and 71% (10). Two other prevalence studies identified clinically significant depressive symptoms in 42-57% of COPD patients (11, 12). A cross-sectional study guided in USA, assessed for depression 1736 patients with COPD and the results showed that 40% of the patients had three or more depressive symptoms. These symptoms were more common in patients with COPD than in patients with coronary heart disease, stroke, diabetes, hypertension and cancer (13).

A case-control study published in 2002, evaluated 676 subjects with COPD and showed that the prevalence of depression in patients with severe COPD was 25% compared to 19.6% in patients with mild to moderate COPD, and 17.5% in controls. The risk of depression was 2.5 times higher for patients with severe COPD than for controls, these results highlighting the importance of reducing depressive symptoms from the early stages of COPD (14). Worsening COPD status can be associated with higher prevalence of anxious symptoms (15). As well, it was revealed that depression after hospitalization for COPD is frequently associated with a significantly increase in mortality (16, 17).

Despite the magnitude of the problem, depression in COPD patients could be very difficult to recognize, due to the lack of specific symptoms, the depressive symptoms being often attributed to the underlying pulmonary disease (14, 18).

Common mechanisms for explaining the association of anxiety and COPD include cigarette smoke exposure, physical inactivity, social isolation, multiple episodes of dyspnea and chronic hypoxia, all contributing to the appearance of depressive symptoms in patients with chronic lung disease (5).

A multicentre prospective study followed 416 patients hospitalized for the acute exacerbation of COPD and discovered that anxiety was more common in women than in men (47% vs. 34%) and current smokers had a higher prevalence of both depression and anxiety than non-smokers patients (19). An article published

in 2004, showed possible explanatory models for a common pathophysiology between COPD and anxiety, including the hyperventilation model and cognitive-behavioral model (20) and in 2005, a Slovenian study revealed a direct connection between the perception of dyspnea and anxiety or depression (21).

Anxiety and depression are also important factors in disease-specific health-related quality of life and hospitalization rates, exacerbations of the pulmonary disease being the main cause for hospitalization in patients with COPD (3, 4). The presence of anxiety and/or major depressive disorder is an important risk factor for the exacerbation of symptoms and re-hospitalization within a 12-month period in patients with chronic lung disease and poor health-related quality of life (3, 22). Also, many studies identify that depression and anxiety in COPD patients lead to a lower quality of life, poorer health status and decreased adherence to treatment. Several studies have shown improvement in psychiatric symptoms after following the pulmonary rehabilitation program (23).

Epidemiological studies often show conflicting results regarding the prevalence of psychiatric disorders in COPD patients, these differences being dues to the variables assessment instruments.

CLINICAL ASSESSMENT OF PSYCHIATRIC DISORDERS IN COPD

An appropriate clinical approach of COPD patients has to identify the early symptoms of psychiatric disorders, as well the risk factors and the parameters associated with these symptoms.

There are several studies that revealed some risk factors for anxiety and/or depression in chronic pulmonary patients. For instance, a recent cross-sectional study including 122 patients with stable COPD reached the conclusion that increasing stage in BODE index is a predictor for anxious symptoms (24), BODE index being a multidimensional grading system, comprising the body-mass index, distance walked in 6 minutes (6-minute walk test), the degree of airflow obstruction (FEV_1), and score on MMRC dyspnea scale, predicting the mortality among patients with COPD (25). Another study including 84 patients diagnosed with COPD showed that the following parameters were generally associated with depression: GOLD stage, BODE index, the percent of the predicted value of FEV_1 and modified Medical Research Council (MMRC) dyspnea score (26).

A group of Turkish researchers conducted a recent trial and concluded that the major risk factor for anxiety and depression is dyspnea; also, the cytologic examination of bronchoalveolar lavage appeared to be an useful tool for identifying patients with psychiatric disorders because it shows the extent of the lung damage, which is the major mechanism underlying dyspnea (27).

A prospective cohort study including 1205 patients, with up to 30 years of follow-up, reached the important conclusion that a poor lung function is a risk factor for depression, particularly in patients with prevalent chronic disease (28).

These arguments derived from clinical studies and the well-known increased prevalence of anxiety and major depressive disorder in patients with chronic obstructive lung disease support the development of a screening strategy in patients with chronic respiratory disorders.

Screening for depression usually use

"PHQ-9 Depression Questionnaire", a self-report 9-item questionnaire, resulting in a score, quantifying the severity of depression. For anxiety, "Hamilton Anxiety Rating Scale" requires a short time to apply it and to analyze the answers (29). Both screening questionnaires should be applied in patients with chronic lung disease admitted in hospitals, pulmonary rehabilitation centers or in outpatients, at their regular pulmonologist visit.

This psychiatric assessment is highly recommended in COPD patients as it enables the clinician to identify patients who need undergo a more appropriate diagnostic interview and also the high-risk patients.

THERAPEUTIC APPROACH – SPECIFIC ISSUES

When anxiety and/or depression are diagnosed in the setting of a chronic obstructive pulmonary disease, there are several difficult issues regarding the therapeutic approach.

For anxiety, pharmacological treatment is one of the most convenient choices. The most common course of treatment is the use of serotonin-reuptake inhibitors (SSRI), which decreases the perception of dyspnea. Citalopram and escitalopram are preferred because they have an advantage in patients taking multiple drugs, having the lowest potential to interfere with cytochrome P450 system (30).

Benzodiazepines, such as clonazepam or alprazolam, have anxiolytic effects and they are used to treat anxiety, but they could interfere with central respiratory drive, leading to respiratory depression. Furthermore, these drugs have increased rates of withdrawal symptoms and a half or a quarter of the usual starting dose is recommended in respiratory patients (30).

Patients who do not respond to this treatment are ideal candidates for psychotherapy, delivered under multiple forms: cognitive-behavioral therapy, interpersonal therapy or problem-solving therapy (31). In patients with chronic lung disease, the addition of psychotherapy and pulmonary rehabilitation program has been demonstrated to decrease anxiety (32).

Moreover, choosing an antidepressant for patients with COPD is a very difficult matter and depends on the pattern of depression. It is very important that in patients with chronic lung disease the selected medication not to have as therapeutic effect sedation, because respiratory depression is an important potential side-effect of psychotropic medication. In this regard, it is recommended to use SSRIs or newer antidepressants, such as venlafaxine, duloxetine and mirtazapine (33).

CONCLUSION

Anxiety and depression are co morbidities often present in the clinical presentation of patients with chronic obstructive lung disease, requiring diagnosis and appropriate treatment. As there are no laboratory findings to confirm these diagnoses, increased awareness of healthcare providers and screening tools are important steps in managing psychiatric disorders in pulmonary patients.

The correlation between chronic lung disease and psychiatric disorders is very complex, including somatic, psychological and social factors. Nowadays it is possible to successfully treat psychiatric disorders associated with chronic lung disease, thus improving the quality of patient's life, lowering the costs associated with hospitalization and improving patient's role in the society.

Further studies are needed to clarify the pathogenic mechanisms underlying the association COPD – psychiatric disorders and to evaluate the effects of new treatment options so that the clinical guidelines can be renewed periodically.

NEWS

DOES WEIGHT MISPERCEPTION HAVE AN

IMPACT ON EATING BEHAVIOR?

A recent study among spanish adolescents had shown that females tend to perceive themselves as being overweight when in fact their body mass index is between normal limits. On the other hand, the majority of people who consider that they have normal weight, but in reality they are overweight, are males. There has been spotted another difference between genders in reported physical activity. It seems that males are more physically active than females. Moreover, females often go on a diet only for aesthetic reasons. The conclusions of the study are that the misperception of weight results in eating disorders. For example, if a person considers that is overweight at a normal BMI value, will follow an unfit diet, low in vitamin, minerals and macronutrients. A desired outcome is to provide better nutritional education from a young age since eating disorders are related to low self-esteem and ill general health. (Jáuregui-Lobera I, Ezquerra-Cabrera M, Carbonero-Carreño R, Ruiz-Prieto I, Weight misperception, self-reported physical fitness, dieting and some psychological variables as risk factors for eating disorders, *Nutrients* 2013; *5*: 4486-4502).

EVALUATION OF STUDENT PERCEPTION OF THE LECTURE "ORAL FUNCTIONAL MEDICAL REHABILITATION: BALNEOPHYSIOTHERAPY"

S.I. Stratulat, C. Dombici, Doriana Forna
University of Medicine and Pharmacy "Grigore T. Popa"-Iasi
Faculty of Dental Medicine
Department of Implantology
Discipline of Rehabilitative Medicine-Balneophysiotherapy

EVALUATION OF STUDENT PERCEPTION OF THE LECTURE "ORAL FUNCTIONAL MEDICAL REHABILITATION: BALNEOPHYSIOTHERAPY" (Abstract): The **aim** of the study was to assess this course as perceived by the 6th year dentistry students. **Material and methods:** Applying and validating the "Dundee Ready Education Environment Measure (DREEM)" for the first time in Romania. **Results and discussion:** The reliability of the test according to Cronbach alpha method, which measures the internal consistency of a test, was 0.87 (Cronbach alpha coefficient should be above 0.70). As to the reliability coefficients (internal consistency) for each test subscale and for the entire test, DREEM proved a very good overall reliability, with alpha = 0.89. The reliability of each DREEM subscale was also analyzed. The DREEM test results, with a global score of 149, indicate a "more positive than negative" perception (score between 101 and 150). **Conclusions:** The DREEM test showed that the assessment and treatment of pain in dental-maxillary pathology and TMJ dysfunctions through medical rehabilitation by means of balneophysiotherapy is of interest to final year dental medicine students. As a student-teacher partnership, modern education cannot ignore the practical needs of students and should add to their theoretical training with courses and practical training programs necessary in their future profession. **Keywords:** DENTAL EDUCATION, CURRICULUM, ORAL HEALTH EDUCATION, MEDICAL REHABILITATION, TEMPORO-MANDIBULAR JOINT, FUNCTIONALITY

The curriculum for the 6th (final) year students of the Iasi Faculty of Dentistry has included since 2004 the course in "Oral Functional Medical Rehabilitation: Balneophysiotherapy", aimed at helping students acquire the methodology for rehabilitation treatment of orodental and craniofacial pain, as well as temporomandibular joint (TMJ) dysfunctions (1).

The Romanian Society of Physical and Rehabilitation Medicine, second in Europe after France (2, 3), was founded in 1922 and the use of mineral waters in the preventive treatment of periodontal inflammatory conditions has been introduced in Romania since 1987, by the WHO Romania Centre for Infant Oral Rehabilitation and the Academy of Medical Sciences of Romania at Baltatesti Resort, Neamt county (2). This was achieved in correlation with WHO guidelines on oral health and prevention in dentistry (4), as well as the European direc-

tives for healthy aging and physical activity with adequate nutrition for old age (3).

The course curriculum consists of 10 2-hour lectures and 20 2-hour practical works at patient's bedside; the students fills in an observation sheet for orodental diagnosis and general medical condition based on current clinical and laboratory investigations.

MATERIAL AND METHODS

The test has 50 items and assesses the environment in which future doctors are trained (5), and also the efficiency, degree of interest and perceived importance of the course and practical works among students, using the 4-point Likert scale, with the following options: *Strongly agree, Agree, Uncertain, Disagree, Strongly Disagree*.

Of the total 185 final year dental students, 174 students, of which 23 foreign students, were asked to fill in the assessment test, an adaptation of the Dundee Ready Educational Environment Measure (DREEM) test in a paper-pencil survey, on the course and practical works in "Oral Medical Rehabilitation: Balneophysiotherapy" upon course completion. The questions targeted student perception, expectations, attitude, interest and satisfaction in the course and practical works. The test was written in its original template; written informed consent from all participants and hospital ethics committee approval in accordance with Helsinki declaration were obtained.

This is an important aspect of medical education, being rather neglected in dental educational research. The aim of the study was to fill this gap by applying and validating for the first time the DREEM test in a Romanian-speaking sample of dental medicine students (6, 7, 8, 9). Student responses were used to quantify educational effectiveness and their attitude regarding the information acquired during the course and its usefulness in their training as future dentists (6, 10, 11, 12).

RESULTS AND DISCUSSION

The questionnaire assesses 5 subscales, each with a different interpretation, as follows. The maximal score for the DREEM test is 200, indicating an ideal educational environment; minimum test score is 0. Items 4, 8, 9, 17, 28, 35, 39, 48 and 50 are negative scores; therefore, the scores for these items should be reversed in order to obtain the total score by summing up the subjects' responses to all the items of the test/ **all item responses**.

The test is divided into 5 subscales:

- *Students Perception of Learning* contains items 1, 7, 13, 16, 20, 22, 24, 25, 38, 44, 47 and 48, maximum score 48. The obtained score was 35, and the interpretation was: 25-36 "A more positive perception";
- *Students Perception of Course organizers* contains items 2, 6, 8, 9, 18, 29, 32, 37, 39, 40 and 50. The obtained score was 33, and the interpretation was: 23-33 "Moving in the right direction";
- *Students Academic Self-Perception* subscale contains items 5, 10, 21, 26, 27, 31, 41 and 45. The obtained score result was 24, and the interpretation was: 17-24 "Feeling more on the positive side";
- *Students Perceptions of Atmosphere* subscale contains items 11, 12, 17, 23, 30, 33, 34, 35, 36, 42, 43 and 49. The obtained score was 35, and the interpretation was: 25-36 "A more positive attitude";
- *Students Social Self- Perceptions* subscale contains items 3, 4, 14, 15, 19, 28 and 46. The obtained score was 18, and the interpretation was: 15-21 "Not too bad";

The authors of the test reported a good validity and reliability. We analyzed the

reliability and validity of this tool adapted for our course in a dental medicine student sample. Because the test has 5 subscales, for a good content validity, the 5 subscales have to positively correlate with each other. All Pearson *r* correlation coefficients between the 5 test subscales are important, with average and high values (tab. I).

We also analyzed the DREEM reliability using the Cronbach alpha method. A high Cronbach alpha coefficient tells us that the test has high internal consistency, i.e. the test items correlate with each other. For good reliability, Cronbach alpha coefficient should be above 0.70. A reliability coefficient between 0.60 and 0.70 tells us that the test has acceptable reliability; if the reliability coefficient is below 0.60, the test is considered to have a fairly low reliability. The authors reported for the entire test a Cronbach alpha reliability coefficient of 0.87.

TABLE I

Pearson's *r* correlation coefficients for the 5 test subscales

Variables	1	2	3	4	5
1. Students Perception of Learning	1.000	0.575	0.605	0.741	0.490
2. Students Perception of Course organizers		1.000	0.415	0.714	0.405
3. Students Academic Self-Perception			1.000	0.595	0.449
4. Students Perceptions of Atmosphere				1.000	0.535
5. Students Social Self-Perceptions					1.000

In our student sample, the test had a very good overall reliability, with alpha = 0.89. We also analyzed the reliability of each subscale; for the first 4 DREEM subscales, the Cronbach alpha reliability coefficients indicated an acceptable and good validity, whereas for the *Students Social Self- Perceptions* subscale the Cronbach alpha reliability coefficient was low. Therefore, the reliability of the fifth subscale was low, meaning that the degree of confidence in the results obtained through this subscale was low (tab. II, III).

Comparing the obtained average scores to those provided by the authors of the test, we noticed that the average total score entered the category 101-150: more positive than negative.

TABLE II

Reliability coefficients (internal consistence) for each test dimension and for the entire test

Dimensions	No. of items	Cronbach alpha coefficient
Students Perception of Learning	12	0.739
Students Perception of Course organizers	11	0.651
Students Academic Self-Perception	8	0.655
Students Perceptions of Atmosphere	12	0.730
Students Social Self-Perceptions	7	0.319
Total Score	50	0.895

TABLE III
Average scores and standard deviations for each test subscale and for the entire test

Dimensions	No. of items	Average	Standard deviation
Students Perception of Learning	12	31.38	5.52
Students Perception of Course organizers	11	28.67	5.01
Students Academic Self-Perception	8	21.81	3.82
Students Perceptions of Atmosphere	12	31.78	5.84
Students Social Self-Perceptions	7	17.81	2.98
Total Score	50	131.44	18.96

Analyzing the averages for the five DREEM subscales and comparing them to the standards provided by the author, we found that:

- The average score for the *Students Perception of Learning* subscale was interpreted as: 25-36 - a more positive perception;
- The average score for the *Students Perception of Course Organizers* subscale was interpreted as: 23-33 - moving in the right direction;
- The average score for the *Students Academic Self-Perception* subscale was interpreted as: 17-24- feeling more on the positive side;
- The average score for the *Students Perceptions of Atmosphere* subscale were interpreted as: 25-36 - a more positive attitude;
- The average score for the *Students Social Self-Perceptions* subscale was interpreted as: 15-21-not too bad.

The above data show that for both the entire test and for each test subscale students perception was positive, which means that they appreciate the course.

CONCLUSIONS

The analysis of test results demonstrates students' interest and appreciation of the knowledge and practical skills acquired during this course. The test identified the need for practical work in the general medical pathology to be illustrated by clinical cases and to be carried out individually by students in Dental Medicine. Also, the university curriculum for the final years of study should be adapted according to the changes in dental pathology, in keeping with updated information, so that to meet the four goals:

1. Tailor treatment to the individual patient, and thus to receive the best treatment;
2. Transfer research findings to the practicing dentist, because they are the main caregiver of patients with **TMJ dysfunction**;
3. Balance the judgment of best research evidence with clinical expertise in the choice of treatment;
4. Gain more information about patient preferences and values and what impact this has on treatment outcome.

ACKNOWLEDGEMENTS

SIS has made substantial contributions to conception, analysis and interpretation of data. He has been involved in drafting the manuscript and revising it critically for important intellectual content. The author has read and approved the final manuscript.

NEWS

INCREASED EXPRESSION OF ANTIMICROBIAL PEPTIDES AND TLR IN TINEA AND PITYRIASIS VERSICOLOR

A study by Brasch *et al.* investigated the role of non-cellular factors in the epidermal defence against fungi that cause superficial tinea or pityriasis versicolor, based on the observation that these pathogens are usually confined to stratum corneum. Using immunostainings in skin biopsies, researchers found an increase in expression of defensins 2 and 3 (hBD-2, hBD-3), psoriasin, RNase7, toll-like receptors 2 and 4 (TLR2, TLR4) in certain layers of lesional epidermis when compared to normal skin. In infected epidermis, defensins hBD2 and hBD3 were expressed in the stratum corneum and granulosum, while psoriasin was detected more common in the upper skin layers. However, the expression of TLR9 and dectin 2 showed no significant differences between normal and infected skin. The results of the study demonstrate the presence of antimicrobial peptides and ligands that contribute to fungal containment in tinea and pityriasis versicolor. (Brasch J, Mörig A, Neumann B, Proksch E. Expression of antimicrobial peptides and toll-like receptors is increased in tinea and pityriasis versicolor. *Mycoses.* 2013 Aug 19. doi: 10.1111/myc.12118) .

RISK ASSESSMENT IN THE DEVELOPMENT OF ATRIAL FIBRILLATION AT PATIENTS WITH ASSOCIATE THYROID DYSFUNCTIONS (Abstract): Thyroid hormones are an important regulator of cardiac function and vascular system. Atrial fibrillation is a common cardiac arrhythmia and an important risk factor for the ischemic cerebral vascular accident and heart failure. **Objectives:** The examination of the risk to develop atrial fibrillation in relation to the whole spectrum of thyroid dysfunctions. **Material and methods:** All participants to our study were selected from among subjects with cardiovascular disorders whose hormonal thyroid status had been controlled previously and who hadn't been treated for thyroid functional disorders. Based on these criteria we defined a study lot made up of 791 subjects, 700 women and 91 men, aged between 22 to 86, with a mean age of approximately 60 years old, divided into five groups, based on the level of thyroid hormones. Once the lot was constituted, evaluations were made of the cardiovascular and thyroid condition at 6 and 12 months. **Results:** During monitoring, most patients who developed atrial fibrillation were registered in the groups with manifest clinical hyperthyroidism, 34,62% and respectively with subclinical hypothyroidism, 38,6%. The main risk factors at the patients with manifest clinical hyperthyroidism were: female gender (RR=1.97) and age above 60 (RR=1.33), as well as the presence of coronary disease in the personal pathological record (RR=3.31), HBP (RR=1.46) and cardiac frequency in excess of 80 beats/min (RR=1.38). The main risk factors that led to atrial fibrillation among the patients with subclinical hypothyroidism, were: obesity (RR=2.21), the presence in the personal record of heart disease (RR=2,0), age over 60 (RR=1.90) and female sex (RR=1.30). At the patients who had been administered beta blockers prior to admission (RR=0.99), ACEI (RR=0.85) and/or antiarrythmic drugs (RR=0.54), the medication represented a protective factor against developing atrial fibrillation. **Conclusions:** Thyroid dysfunctions are associated with an increased risk to develop atrial fibrillation, both in the case of clinically manifest and the subclinical manifest forms. These results support long term screening for thyroid dysfunctions for patients with atrial fibrillation. **Keywords:** HYPERTHYROIDISM, HYPOTHYROIDISM, ATRIAL FIBRILLATION.

Many of the symptoms and signs in the sphere of thyroid dysfunctions are due to the effects of thyroid hormones on the cardiovascular system and the hemodynam-

ic modifications that occur (1). Both hypothyroidism and hyperthyroidism trigger cardiovascular modifications which may lead to or worsen heart failure, atrial fibrillation, and pectoral angina. The fact is the more important as the prevalence of thyroid dysfunctions is estimated at 9-15% (2).

The main effects of thyroid hormones on the heart and peripheral vascular system are represented by the decrease of peripheral vascular resistance and the increase of heart frequency while at rest, the contractility of the myocardium and the increase of the blood flow. Atrial fibrillation represents the most frequent rhythm disorder incurred by the patient with hyperthyroidism, its prevalence being estimated at 2-20% of the patients (3). In addition, atrial fibrillation is responsible for most hospital admissions of the patient with hyperthyroidism.

The purpose of the present study was to evaluate the relationship between thyroid dysfunction and the risk of atrial fibrillation at patients who also associate cardiovascular pathology.

MATERIAL AND METHODS

All participants included in our study were selected from the subjects with cardiovascular disorders who had been controlled in terms of the hormonal thyroid condition in the 3rd Medical Clinic of the "St. Spiridon" University Emergency Hospital,"Grigore T. Popa" University of Medicine and Pharmacy, Iasi and who had not been treated previously for functional thyroid disorders. The study groups were constituted between 2006-2012.

We included both male and female subjects, based on the serum value of free triiodothyronine (FT3), free thyroxine (FT4) and thyroid-stimulating hormone (TSH). After the overnight fast, all patients were subjected to a complete medical evaluation, lab exams, electrocardiogram and echocardiography. Among the exclusion criteria we included: age <18, hypophysis/hypothalamic disorders, pregnancy, specific thyroid treatment received prior to the inclusion in the study. Based on these criteria we defined a study group divided into five lots, based on the level of thyroid hormones: a) 81 patients with subclinical hyperthyroidism (10,2%); b) 165 patients with hyperthyroidism (20,9%); c) 75 patients with subclinical hypothyroidism (9,5%); d) 170 patients with hypothyroidism (21,5%); e) witness - 300 patients with cardiovascular modifications, without thyroid dysfunction (37,9%).

The analysis was conducted using the package *SPSS 13.0* (SPSS Inc, Chicago, Illinois, USA).

RESULTS

At the witness group, 19.4% (58 cases) of the patients showed atrial fibrillation during monitoring, registering a slight decrease of the cases with atrial fibrillation, until the end of this study, at 18% (54 cases) (tab. I, fig. 1). The main risk factors were: female sex (RR=1.99), heart frequency over 80 beats/min (RR=1.56), the LDL-cholesterol above 130 mg/dl (RR=1.55), the presence of heart disease in the personal record (RR=2.86), HBP (RR=1.50), obesity (RR=1.54) and age over 60 (RR=1.40). The treatment with antiarrythmic drugs, administered prior to the inclusion in the study, represented a protective factor (RR=0.80) (tab. II, fig. 2).

Among the patients with subclinical hyperthyroidism, 8.6% (7 cases) showed atrial fibrillation at the beginning of the monitoring period, all with paroxysmal atrial fibrillation, while at the end of the study we registered a percentage of 9.9% of pa-

tients with atrial fibrillation as related to the entire study group (tab. I, fig. 1). The main risk factors identified were: heart frequency over 80 beats/min (RR=4.38), the presence of HBP in the antecedents (RR=4.0) and of heart disease (RR=3.60), increased values of triglycerides (RR=4.18) and age over 60 (RR=3.23). The treatment with antiarrythmic drugs (RR=0.20) and/or beta blockers (RR=0.99) represents a protective factor against the development of atrial fibrillation (tab. II, fig. 2).

TABLE I

Distribution of patients with atrial fibrillation during the monitoring period for thyroid dysfunction

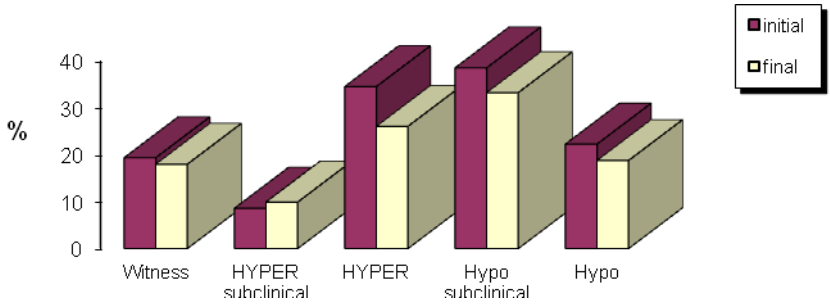

Fig. 1. Distribution of cases with atrial fibrillation depending on the moment of the study

In the group of patients with manifest clinical hyperthyroidism, 34.6 (57 cases) developed atrial fibrillation during monitoring, registering a decrease of the number to 43 cases (26.1%) until the end of the study (tab. I, fig. 1). The main risk factors were: female sex (RR=1.97) and age over 60 (RR=1.33), as well as the presence in the personal records of heart disease (RR=3.31), HBP (RR=1.46) and heart frequency of over 80 beats/min (RR=1.38). The treatment with antiarrythmic, used previously, represented a protective factor for thus study group (RR=0.54) for the development of atrial fibrillation (tab. II, fig. 2).

The main risk factors that led to atrial

fibrillation at the 38.6% (29 cases), with a slight decrease of the number of cases at 25 (33.3%) (tab. I, fig.1), among the patients with subclinical hypothyroidism, were: obesity (RR=2.21), the presence in the personal record of heart disease (RR=2,0), age over 60 (RR=1.90) and female sex (RR=1.30). At the patients who had been administered beta blockers prior to admission (RR=0.99), ACEI (RR=0.85) and/or antiarrythmic drugs (RR=0.54), the medication represented a protective factor against developing atrial fibrillation. (tab. II, fig. 2).

TABLE II

Risk factors in developing atrial fibrillation as compared on study lots

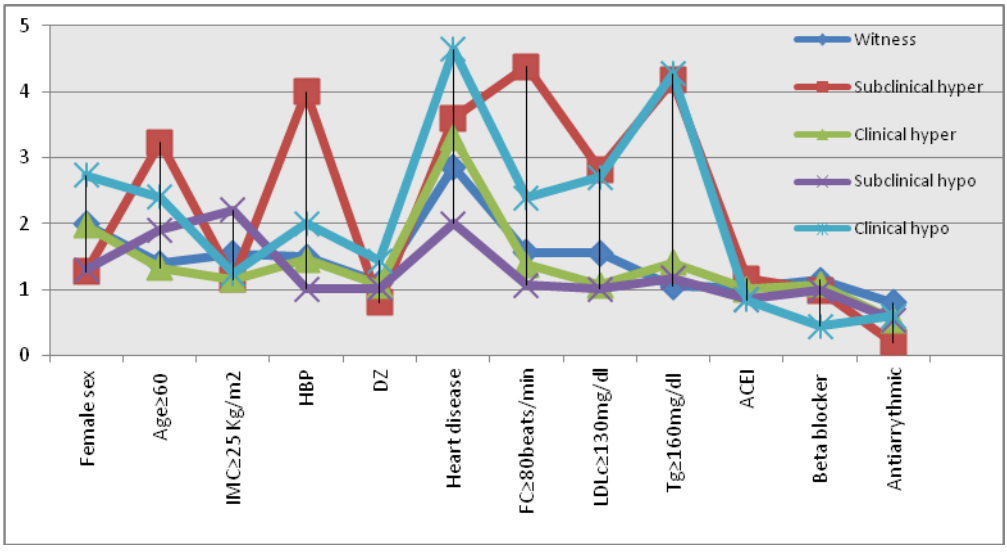

Fig. 2. Relative risk of atrial fibrillation on study lots

Among the patient with manifest clinical hypothyroidism, 22.3% (38 cases) showed atrial fibrillation during monitoring, with a slight decrease of the number to 32 cases (18.8%) (tab. I, fig. 1). The main risk factors identified were: increased levels of triglycerides (RR=4.27) and of LDL-cholesterol (RR=2.70), female sex (RR= 2.73) and age over 60 (RR=2.40), the presence of heart disease in the personal record (RR=4.64), HBP (RR=2.0) and hyperglycemia (RR=1.44), heart frequency of over 80 beats/min (RR=2.39) and obesity (RR= 1.24). ACEI (RR=0.84), antiarrythmic drugs (RR=0.60) and/or beta blockers (RR=0.44), administered prior to the inclusion in the study represent protective factors against developing atrial fibrillation in this study group (tab. II, fig. 2)

At the patients with atrial fibrillation from the lot with subclinical hyperthyroidism, data shows the efficiency of the ACEI treatment and beta blockers.

At the patients with atrial fibrillation from the lot with clinical hyperthyroidism, the most efficient treatment consisted in beta blockers and thyroid treatment (tab III).

TABLE III

Treatment of patients with thyroid dysfunction and atrial fibrillation

Atrial fibrillation (AF)	Witness (n=58)		HYPER subclinical (n=7)		HYPER (n=57)		Hypo Subclinical (n=29)		Hypo (n=38)

Thyroidian treatment										
	-	-	4	57,1%	56	98,2%	22	75,8%	38	100%

At the patients from the lot with subclinical hypothyroidism, the treatments used for atrial fibrillation showed the efficiency of thyroid treatment accompanied by hypolipidemic treatment and antiplatelet.

At the patients with atrial fibrillation from the lot with clinical hypothyroidism, the most efficient treatment consisted in thyroid treatment associated with hypolipidemic and antiplatelet (tab III).

DISCUSSION

Atrial fibrillation represents the most common rhythm disorder incurred by the hyperthyroid patient and is responsible for most hospital admissions of the patient with hyperthyroidism. In a study that included a number of 40,628 patients with

hyperthyroidism, the prevalence of atrial fibrillation was of 8.3%, and the most important risk factors for the development of atrial fibrillation were male sex, ischemic heart disease, valvulopathy and congestive heart failure. These data are partially consistent with the results of our study, which showed as an additional risk factor old age and female sex. What is of importance is that subclinical hyperthyroidism is associated with the same risk of developing atrial fibrillation as the manifest clinical hyperthyroidism (4,5). It is also to be noticed that the prevalence of hyperthyroidism at the patients with newly developed atrial fibrillation is of 1%, which is very low (6). Nevertheless, if we take into consideration patients with atrial fibrillation of unknown causes, the prevalence of atrial fibrillation is of 13%. Thus, there raises the question, whether thyroid hormones should be dosed for all patients who show atrial fibrillation with a recent debut. Although the probability that hormonal tests be abnormal at patients with atrial fibrillation of recent debut is small, these tests are nonetheless recommended, due to the great conversion rate at sinus rhythm after the euthyroid status has been restored (7,8). In our study, the prevalence reached 34.6% at patients with hyperthyroidism.

If in the case of hyperthyroidism the most frequent arrhythmias are the atrial ones, especially atrial fibrillation, in the case of hypothyroidism the most frequent arrhythmias are of ventricular origin (8, 9, 10). The results of our study showed an increased risk to develop atrial fibrillation in the lots with manifest clinical hypothyroidism, but especially in the lot with subclinical hypothyroidism, which is inconsistent with the data in the literature, interpreted as being correlated with old age, the presence of heart disease at a large number of patients and the association of other cardiovascular factors.

The treatment of atrial fibrillation observes the three general principles: control of rhythm, control of heart frequency and prevention of thromboembolic complications. The date in our study showed the efficiency of medication, especially beta blockers, at patients with hyperthyroidism but also the efficiency of a specific thyroid treatment for both hyperthyroidism and hypothyroidism, in agreement with the literature data (7). The use of anticoagulant treatment at patients with hyperthyroidism and atrial fibrillation has been amply debated. As in the atrial fibrillation of different origins, the risks and benefits of the anticoagulant treatment need to be balanced, taking into consideration the hemorrhagic and thromboembolic complications (11). There are studies which showed that old age and not atrial fibrillation is the greatest risk factor at these patients to develop a cerebral vascular accident (12). Thus, it is recommended to apply various scores to assess the bleeding risks or thromboembolic complications and the individualized approach of each patient depending on the risk factors and associated co morbidities (11). In addition, the administration of aspirin represents a safer alternative to prevent thromboembolic complications at patients with fewer risk factors. In this light, the results of our study are correlated with what has been previously stated.

The fast diagnosis of hyperthyroidism and hypothyroidism, with the reinstallation of euthyroid status is associated with the recovery of sinus rhythm in most cases within 2-3 months (10, 13, 14). Patients older than 60 and those with atrial fibrillation of a longer history have a lower rate of

spontaneous conversion to sinus rhythm, in correlation with the data obtained in our study, both in the case of patients with hyperthyroidism and hypothyroidism. Thus, it is recommended to institute a therapeutic approach, either pharmacological or electrical, to reestablish sinus rhythm once hyperthyroidism or hypothyroidism has been corrected. It has been noticed that after the euthyroid condition and conversion to sinus rhythm have been restored, these patients remain in sinus rhythm for a longer period of time.

CONCLUSIONS

There is a direct relationship between the degree of thyroid dysfunction and the risk to develop atrial fibrillation. Our results showed that even the subclinical forms of hyperthyroidism or hypothyroidism were associated with an increased risk of atrial fibrillation. These results indicate long term screening for thyroid dysfunctions in case of patients with atrial fibrillation and the early initiation of endocrinelogical treatment.

PHENOTYPIC VARIABILITY IN PATAU SYNDROME (Abstract): Patau syndrome has an incidence of 1/10.000-20.000, the clinical diagnosis being suggested by the triad cleft lip and palate, microphthalmia / anophthalmia and postaxial polydactyly. Most frequent cytogenetic abnormality is free and homogeneous trisomy 13 (80.0%), rarely being detected trisomy mosaics or Robertsonian translocations. The objective of the study was to identify phenotypic features of trisomy 13. **Material and Methods***:* The retrospective study was conducted on a trial group of 14 cases diagnosed cytogenetically with trisomy 13 between January 2000 and December 2012 at Iasi Medical Genetics Centre. **Results***:* Of the 14 cases, 3 were evaluated pathologically (two aborted foetuses and one stillborn), 8 cases were detected in the neonatal period, and 3 in infancy. Clinical diagnosis was supported by the identification of a model of abnormal development, mainly characterized by: maxillary cleft (lip and palate - 5 cases; lip - 1 case), ocular abnormalities (microphthalmia/anophthalmia - 7 cases; cyclopia - 1 case), postaxial polydactyly (7 cases), scalp defects (6 cases), congenital heart anomalies (10 cases, 6 patients with atrial septal defect), complete holoprosencephaly (4 cases), ear abnormalities (11 cases), broad nasal root (10 cases). An important issue in confirming the phenotypic variability of Patau syndrome is that the classic clinical triad was identified only in one case. **Conclusions***:* Patau syndrome is a disease with variable expression and is characterized by a pattern of abnormal prenatal development characterized by facial dysmorphia, polydactyly and severe birth defects (heart, brain) that generate an increased in utero and perinatal mortality. **Keywords***:* PATAU SYNDROME, TRISOMY 13, CLEFT LIP AND PALATE, MICROPHTHALMIA, POLYDACTYLY, CARDIAC DEFECTS.

Patau syndrome is caused by trisomy 13, the chromosomal etiology being identified by Patau*et al* (1960) (1). Trisomy of chromosome 13 has a different frequency in different stages of ontogenetic development. The chromosome 13 disomy was detected in 0.12% of sperm cells (2). Expression of severity of trisomy 13 is proven by the decrease of its incidence during pregnancy from 5.7% in products of abortion (3), to 0.004% in newborn deaths (4,5) and 0.0002% in living neonates (6).

Patau syndrome is a plurimalformative syndrome whose cardinal signs are cleft lip/palate, microphthalmia/anophthalmia and postaxial polydactyly. Other signs are

scalp defects, holoprosencephaly, congenital heart anomalies (7).

In most cases it is a free homogeneous trisomy, the extra chromosome having in 90% of cases a maternal origin (8). Maternal origin of extra chromosome 13 was detected also in 13 mosaic trisomy (9).

MATERIAL AND METHODS

Our study was a retrospective clinical and cytogenetic one performed on a group of 14 cases of Patau syndrome, cytogenetically confirmed between 2000 and 2012 at Iasi Medical Genetics Centre.

RESULTS

We identified three cases diagnosed postmortem (2 aborted and stillborn) and 11 cases diagnosed in the neonatal period. Most cases were female with sex ratio ♀: ♂ = 10:4.

The clinical elements that supported the clinical diagnosis of Patau syndrome (tab. I, fig. 1) were: abnormal ears (11 cases), cardiac abnormalities (10 cases), flattened nasal root (10 cases), ocular abnormalities - microphthalmia, anophthalmia, cyclopia - (8 cases), polydactyly (7 cases), cleft lip/palate (6 cases), scalp abnormalities (6 cases). Although the clinical diagnosis of Patau syndrome is supported by the triad cleft lip/palate, microphthalmia/anophthalmia and postaxial polydactyly, the combination of the three cardinal signs was identified only in one case, while in two cases we found no cardinal sign. The presence of two major signs was discovered in five cases, and a single sign, usually cleft lip was present in 6 cases.

TABLE I

The clinical features of patients with Patau syndrome

Clinical sign	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10	C11	C12	C13	C14
HPE	+	+	+	+	-	-	-	-	-	-	-	-	-	-

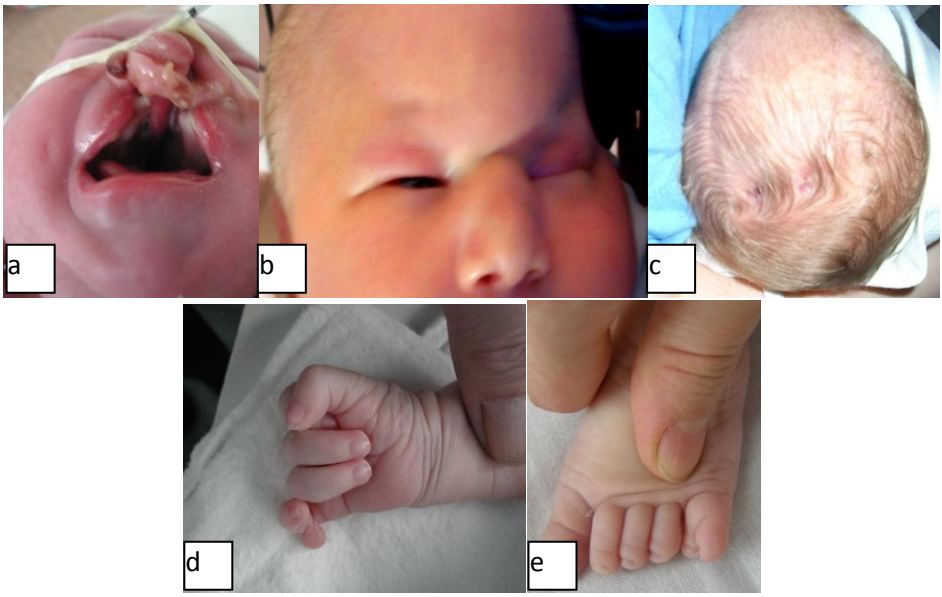

Fig. 1. Clinical signs of Patau syndrome: a. cleft lip and palate; b. anophthalmia and microphtalmia, flattened nasal root; c. scalp defect; d. hand postaxial polydactyly; d. foot postaxial polydactyly

Clinical diagnosis was confirmed by chromosomal analysis: a free homogeneous trisomy 13 - 47,XX(XY),+13 (11/14 cases), a mosaic trisomy 13 - 47,XY,+13/46,XY (1/14), a Robertsonian translocation trisomy 13/14 - 46,XX,rob(13;14)(q10; q10),+13 (1/14) and a homogeneous trisomy 13 associated with a complex abnormality 47,XX,+13/48,XX,del(2)(p11.2→pter),i(2p),+13[29]/[2] (1/14).

DISCUSSION

Patau syndrome is a rare chromosomal disorder that affects approximately 1/10.000 - 1/20.000 births. The disease is severe and in most cases produces a miscarriage or prenatal/perinatal death (7). Clinical diagnosis is based on suggestive signs and symptoms, but the disease has variable expressivity, which can sometimes complicate the diagnostic process. Using these as a starting point, we tried to identify these variable elements based on a relatively large study group - 14 cases.

We found a sex ratio ♀: ♂ = 2.5, aspect which is discordant in relation to most studies of literature. Thus, Alberman et al. (10), analyzing 985 cases of trisomy 13 are found mainly in the case of male patients, while Huether et al. (11) found a sex ratio ♀: ♂ = 0.9 (293 patients) and Bugge et al. (8) found a sex ratio ♀: ♂ = 0.73 (82 cases) (8,10,11). This discrepancy could be related to the small size of the study group, because similar results were cited by Moerman et al. (12) who found a sex ratio ♀: ♂ = 2 on a sample of 12 cases (12).

The most serious malformations of Patau syndrome are the anomalies of the central nervous system. The most severe is holoprosencephaly (HPE) a separation defect of structures from midline of cephalic extremity. It can affect the brain (one cerebral hemisphere, unique cerebral

ventricle, agenesis of the corpus callosum), ocular structures (microphthalmia/ anophthalmia or cyclopia) and frontal bud (proboscis, hypotelorism, velo-palatine median cleft). In minor forms, the only clinical manifestation is single central maxillary incisor (13). HPE is identified in 1/10.000-15.000 live newborns, 1/8.000 foetuses and 1/250 embryos, which indicates that most cases are spontaneously aborted (14, 15). Although aetiology is complex, about two fifths of the cases have a chromosomal aetiology and in 75% of them complained of a trisomy 13 (15-17). In our study, HPE was present in 4/14 cases (28.57%), in two cases being a semilobar form, and in the other two cases was an alobar form (more severe). Our data is consistent with the literature indicating that HPE in Patau syndrome is detected in 17-39% of cases (18, 19). However, pathological examinations of cases of trisomy 13 have shown a frequency of 67% for HPE aspect that could be correlated with lethality of this trisomy (20).

There are three types of HPE: alobar, lobar and semilobar. The most severe form is the alobar form, usually associated with defects of the face (cyclopia/anophthalmia and proboscis), while semilobar forms are accompanied by less severe facial changes (cleft, hypotelorism, flattening of the nose) (21). We also identified such a correlation in the two cases with alobar HPE which presents anophthalmia. However, this correlation is not always relevant, an aspect suggested by the fact that in our only case with cyclopia and proboscis, HPE has been ansemilobar one instead of alobar.

According to Cassidy HPE presence is a negative prognostic factor in trisomy 13 (7). We identified one such feature ourselves, because the four cases of HPE have been identified in the two abortions, the stillbirth and in a patient who died in the neonatal period.

Microphthalmia is a rare congenital anomaly, affecting about 14/100,000 newborns, while anophthalmia is four times more rare (3/100,000 neonates) (22). In about 16% of cases of anophthalmia/microphthalmia is a chromosomal etiology, trisomy 13 being the main abnormality. This type of congenital anomaly is present in 60-70% of cases of Patau syndrome (14, 22). In our study group these abnormalities were detected in 50% of cases, consistent with literature data point, microphthalmia being present in four cases and anophthalmia in three. Another anomaly was iris coloboma, detected in two patients, in one case being associated with microphthalmia.

Polydactyly is a relatively common congenital anomaly being detected in 1:1000 - 1:2000 births. The presence of polydactyly in Patau syndrome is one of the key elements of diagnosis, being found in 60-70% of cases (14). In our study, polydactyly was present in half of patients. In all 7 cases it was hand polydactyly, and 3 of these patients had also foot polydactyly. The bilateral form was more frequent than unilateral one (5 cases versus 2 cases) (23).

Cardiac defects are a characteristic element of trisomy 13 and were present in 80% of patients (7, 14). The most common cardiac abnormalities are atrial septal defect (ASD) and ventricular septal defect (VSD). We have identified cardiac abnormalities in 71.42% of the cases (10/14). Heart defects were isolated or associated. ASD was the most common defect (6/14). Other cardiac abnormalities were: patent ductusarteriosus (2/14), VSD (2/14), dextrocardia (2/14), transposition of great

vessels (1/14), starting point of the aorta in right ventricle (1/14), pulmonary stenosis (1/14), coarctation of the aorta (1/14). In most cases, cardiac abnormalities are not very serious and are not the cause of death. Musewe (24) indicated that only 6% of patients with trisomy 13 had a potentially lethal cardiac anomaly in the first two years of life (24). We identified a similar issue - a potentially lethal anomaly (transposition of great arteries) which is associated with VSD and DSA detected in one of the products of abortion.

Cleft lip and palate and the isolated ones are common abnormalities, detected in 1/700-1/1000 newborns. In most cases (80%) the anomaly is unilateral (usually left). On the other hand, the prevalence of cleft palate is 4/10,000 live births (14). Clefts lip and palate may be associated in 28-37% with other congenital anomalies. Cleft lip and palate is a common malformation in Patau syndrome and is found in 60-70% of cases (25, 26). The frequency of this anomaly in the studied group was 42.85%, cleft lip and palate being found in 6 patients. In four patients the cleft was bilateral and in two cases it was associated with holoprosencephaly.

Scalp defect (aplasia cutis) is a rare congenital anomaly that affects the epidermis, dermis and subcutaneous tissue, located mostly at the vertex. The aetiology may be varied; trisomy 13 being one of the most common chromosomal causes (27). Detection of the anomaly in 6 of our patients is also an argument for this statement.

Nasal abnormalities are common in Patau syndrome, the less severe defect was broad nasal root. In fact in our study this anomaly was discovered in 71.42% of cases (10/14). Serious forms of abnormalities of the nose, such as proboscis or single nostril were rare (3 cases) and were correlated with the presence of holoprosencephaly.

Ear abnormalities are a common condition in Patau syndrome, but in most cases are present only form anomalies of the external ear. We identified such a situation in 78.57% of cases (11/14). Only two patients had a unilateral external auditory canal atresia.

Severe deficiency of intellectual development was identified in all patients after the neonatal period (7). Such a deficit was found in all three infants in our study.

Clinical diagnosis of Patau syndrome should be completed with chromosome analysis, whose results allow calculation of risk of recurrence. Thus, the risk of recurrence is <1% for free trisomies. In the case of inherited Robertsonian translocation the risk is ~ 10% when translocation involved non homologous chromosomes and 100% if the involved two chromosomes 13 (28, 29). For our study, cytogenetic results showed 12 cases of free homogeneous trisomy 13, one case of mosaic trisomy 13 and 1 case of trisomy 13 by de novo Robertsonian translocation, issues consistent with the literature where the frequency of free homogeneous trisomy 13 is over 90% and a frequency of trisomy by Robertsonian translocation is 5-10% (14). Given the absence of inherited chromosomal abnormalities we have estimated that the risk of recurrence is <1% in all 14 cases.

CONCLUSIONS

Patau syndrome is a severe chromosomal condition but with a polymorphic clinical picture, which may cause difficulties in clinical diagnosis. Although, the diagnosis is confirmed by a specific clinical triad - cleft lip and palate, microphthal-

mia/anophthalmia and postaxial polydactyly – we discovered such association in only one case, while two patients had none of these clinical elements. Holoprosencephaly spectrum is the most severe, being associated with increased in utero and perinatal mortality. Knowing phenotypic variability, the detection of atypical cases is important for a correct clinical management.

NEWS

ANTIBACTERIAL PROPERTIES OF *GARCINIA NOBILIS*

The emergence of multidrug resistance in bacteria has highlighted the need to find new bioactive compounds. A study by Fouotsa *et al.* aimed to search whether Garcinia nobilis, Oricia suaveolens and Balsamocitrus camerunensis contain constituents active against multidrug resistant bacteria. Twenty-two compounds isolated from the three medicinal plants and the crude extracts were tested against *Mycobacterium tuberculosis* and Gram-negative bacteria. MIC (minimal inhibitory concentrations) and MBC (minimal bactericidal concentrations) were determined. *G. nobilis* extract showed better anti-tuberculosis and antibacterial activities than O. suaveolens and B. camerunensis. The crude extract of G. nobilis exhibited inhibitory effects against 12 of the 14 tested bacteria. The results also indicated that some of the compounds isolated, especially 4-prenyl-2-(3,7-dimethyl-2,6-octadienyl)-1,3,5,8-tetrahydroxyxanthone, could represent natural antibacterial agents (Fouotsa H, Mbaveng AT, Mbazoa CD *et al.* Antibacterial constituents of three Cameroonian medicinal plants: Garcinia nobilis, Oricia suaveolens and Balsamocitrus camerunensis. *BMC Complement Altern Med* 2013; 13(1): 81).

OVERWEIGHT AND OBESITY IN SCHOOL AGE CHILDREN IN WESTERN ROMANIA (Abstract): Obesity prevalence in both adults and children has reached epidemic proportions worldwide. Romania seems to follow the same trend, but studies proving this fact are scarce. Our **aim** was to determine the prevalence of overweight and obesity and to find correlations to certain health-risk behaviors in children from western Romania. **Material and methods**: In this cross-sectional study, a total of 3626 children aged 7-18 years were examined by medical students (February 2010- June 2011). Children were classified by their body mass index using International Obesity Task Force (IOTF) reference. The children were asked to complete a short questionnaire inquiring about 5 health-risk behaviors: consumption of fast-food, sweetened beverages, sweets and fruits and about physical exercise. **Results**: The overall prevalence of overweight was 18.2% (16.2% in girls and 20.7% in boys) and 7.2% for obesity (5.8% in girls and 9.0% in boys). The prevalence of both overweight and obesity was higher in boys versus girls and rural versus urban. Overweight and obesity was correlated with the consumption of sweetened beverages and sweets and also with sedentary behavior. **Conclusions**: The prevalence of overweight and obesity children is alarming, particularly in boys, higher in rural versus urban. The findings confirm the urgent need for national preventive strategy for childhood obesity and targeted interventions tailored to local circumstances. **Keywords**: OBESITY, OVERWEIGHT, SCHOOL AGE CHILDREN, ROMANIA, IOTF.

Prevalence of overweight and obesity. Prevalence surveys provide important information about the burden of disease and associated risk factors. This information is critical in order to develop effective management strategies. Obesity prevalence in both adults and children has reached epidemic proportions worldwide (1). Romania seems to follow the same trend, but prevalence studies for childhood obesity in Romania are lacking. A search on PubMed, Cochrane Library and World Health Organization reports, failed to find relevant articles regarding prevalence of overweight and obesity in Romania for school-aged children. Obesity has major implications for economical, social and personal welfare, through its direct consequences and the addition of the enormous risk for developing life-threatening diseases and psychological problems. Although there are powerful genetic factors related to the risk

of developing obesity (2), the causes of this epidemic are mainly two: a) an increase in the availability of energy dense food and drink, which promote excessive caloric consumption and b) the advances in technology that indulge a sedentary lifestyle. These issues need to be addressed particularly in the young generation (3).

Heath-risk behaviors. Childhood obesity is an important risk factor for the presence of adult overweight or obesity and the attendant risks of increased morbidity and mortality (4). The role of lifestyle choices have been highlighted in multiple international studies. Information about the interplay between specific health-risk behaviors and their combined effects on obesity are particularly scarce in relevance to Romanian population. Furthermore, Romania is experiencing a rapid health and lifestyle transition and the patterns of daily activity become more similar to those in Western countries (5).

Our aim was to determine the prevalence of overweight and obese and to examine the relationship between obesity and certain health-risk behaviors, in a sample of children in western Romania.

MATERIAL AND METHODS

Demographics. Timis is the largest county in the west part of Romania. According to the National Institute of Statistics, Timis has an area of 8,697 km^2. The young population (0 to 18 years) in Timis county was 156,678 in the 2002 census of population (results from the 2012 census of population are not available at the time of writing) (6). When the present study started, in 2010, in Timis there were 67,146 children attending school in urban setting and 33326 in rural. We randomly chose 5 urban schools (enrolling 5,676 students) and 10 rural schools (enrolling 2653 students) to collected data for this study. The response rate was 50 % urban and 38 % rural. Some students failed to be measured due to various reasons including school absenteeism and conflicting school activities/responsibilities (certain classes were not interrupted for measurement).

Prevalence of overweight and obesity. A total of 3,626 children, aged 7-18 years were examined by medical students, in the period February 2010-June 2011. 108 children were excluded from the database because they were older than 18 or younger than 7. Prior to each data collection round, all examiners were trained in taking accurate measurements, according to international measurement techniques (7). Each child underwent anthropometric assessments that were carried out during one day session. Height and body mass was obtained using calibrated scales. The subjects wore normal, light, indoor clothing without shoes. All anthropometric measurements were taken in the mornings, before lunch time. Children were asked to go to the toilet just before the measurements. The age of children was rounded down when child's age was years and 1-6 months and rounded up when the age was years and 7-12 months. Body mass index (BMI) was calculated as weight (kg)/height (m^2). Children were considered overweight or obese based on International Obesity Taskforce (IOTF) definition (8). International cut off points for body mass index for overweight and obesity by sex between 2 and 18 years are defined by IOTF to pass through BMI of 25 and 30 kg/m^2 at age 18. Cut off points for body mass index for underweight by sex between 2 and 18 years are defined by IOTF to pass through BMI of 17 kg/m^2 at age 18 (9). Although Cole et al defined 3

grades of underweight in his paper; we will further refer as underweight, children that presented a BMI for sex and age below the cutoff of 17 at age 18.

Heath-risk behaviors.

The children were asked to complete, by themselves, a short questionnaire inquiring about 5 health-risk behaviors': consumption of fast-food and pastry, sweetened beverages, sweets and fruits and also about physical exercise. The rating scale from 1 to 5 is shown in table I. The lowest total score (=5) is related to the best practice while the highest (=25) is related to the worst behavior.

TABLE I

Rating scale for the questionnaire 5 health-risk behaviors

Question	Never	1 time /week	2 times /week	3-4 times /week	Daily
How often do you eat fast food or pastry in a week?	1	2	3	4	5
How often do you drink sweetened beverages in a week?	1	2	3	4	5
How often do you eat sweets in a week?	1	2	3	4	5
How often do you do moderate/vigorous exercise in a week?	5	4	3	2	1
How often do you eat fruits in a week?	5	4	3	2	1

Ethical considerations. Because of the non-invasive nature of the protocol consisting only of measurements that are a routine for school examinations (height, weight), we used a "passive consent" or "opt out" method. Parents were fully informed about all study procedures through a school information meeting. Parents who refused the participation communicated this tot the school principal. Prior to the measurement, the child was also asked whether s/he agrees with it. The children's names were not included in the electronic data files. Examiners ensured the basic principles of confidentiality, privacy and objectivity throughout the process. The children were measured in a private room, boys and girls separately. The approval of the University's Ethical Advisory Commission is in accordance with the Helsinki Declaration.

Statistical analysis. Descriptive statistics were run on all the variables. p values of less than 0.05 were considered statistically significant. The prevalence of overweight and obese was determined using the LMS Growth software (10). Data were analyzed using the *SPSS,* PC program (*SPSS version 19.0* - Inc., USA). Binary logistic regression was used to compute odds ratio (OR) with 95% CI for obesity associated with the different life style behaviors. In additional multivariable analyses, we examined the independent effect of each life style factor by mutual adjustment.

RESULTS

Demographics. After excluding 108

children that were younger than 7 or older than 18, a total of 3626 children, aged 7-18 years were examined. The study population consisted of: 1564 boys (43.1%) and 2062 girls (56.9%), with a male/female ratio of 1:1.31. Regarding residence, 2622 children lived in Timisoara and 1004 children in rural surroundings, with an urban/rural ratio of 2.6:1. Age and anthropometric data of the children are presented in table II.

TABLE II
Demographic and anthropometric variables of children

Parameter	Mean +/- Std. Deviation		Range	
	Girls	Boys	Girls	Boys
Age (years)	12.8 (3.17)	12.1 (2.89)	7-18	7-18
Weight (kg)	47.68 (13.91)	49.26 (17.92)	18-126.5	18.5-123
Height (cm)	153.43 (13.87)	154.55 (17.22)	107-188	108-196
BMI (kg/m^2)	19.87 (3.87)	19.9 (4.2)	11.28-45.36	8.08-40.4

Prevalence of underweight, overweight and obesity. In regards to IOTF reference, the overall prevalence for underweight was 10.34% (12.51% in girls and 7.48% in boys, p=0.05), for overweight the overall prevalence was 18.17% (16.29% in girls and 20.65% in boys p=0.2) and 7.17 % for obesity (5.77% in girls and 9.02% in boys; p=0.01) (fig. 1).

The overall prevalence in urban environment of underweight was 3.6% versus 3% in rural (p=0.3), for overweight was 18.3% versus 17.9% in rural (p=0.1), while for obesity was 6.4% in urban and 9.1% (p=0.05) in rural population (fig. 2).

The highest prevalence of overweight was found at ages 10, 11, and 12, while obesity was more prevalent in early ages 7 and 8, slowly decreasing towards 18 years. In regards to underweight our data suggest a higher prevalence at ages 17 and 18, mostly in adolescent girls (fig. 3).

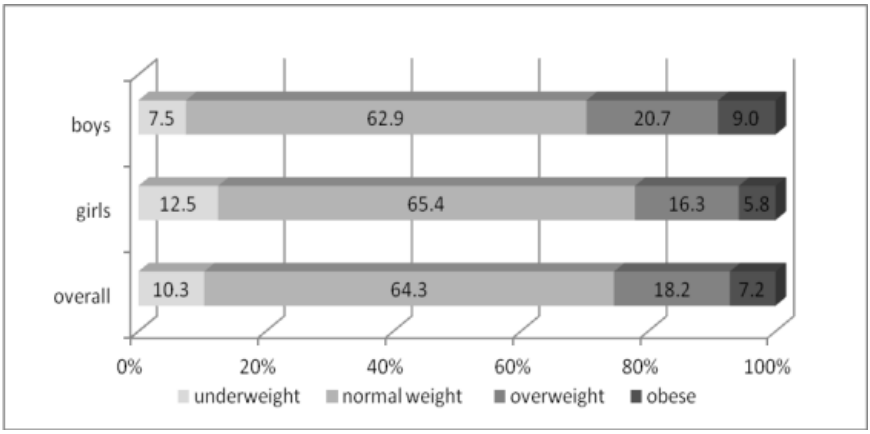

Fig. 1. Prevalence of underweight, overweight and obese in regards to IOTF reference

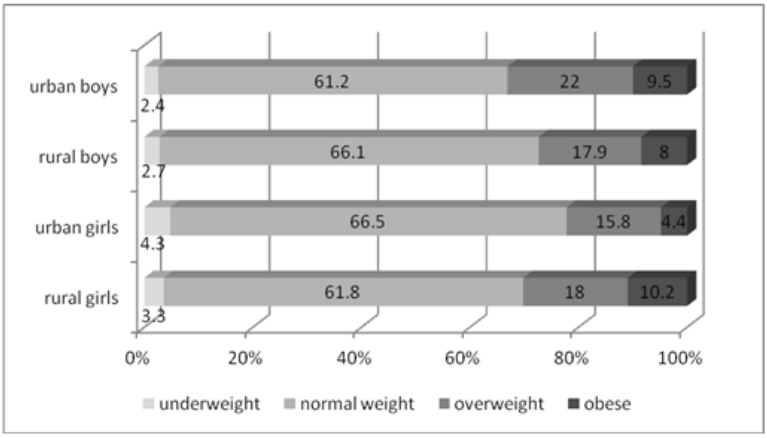

Fig. 2. Prevalence of underweight, overweight and obese in urban versus rural

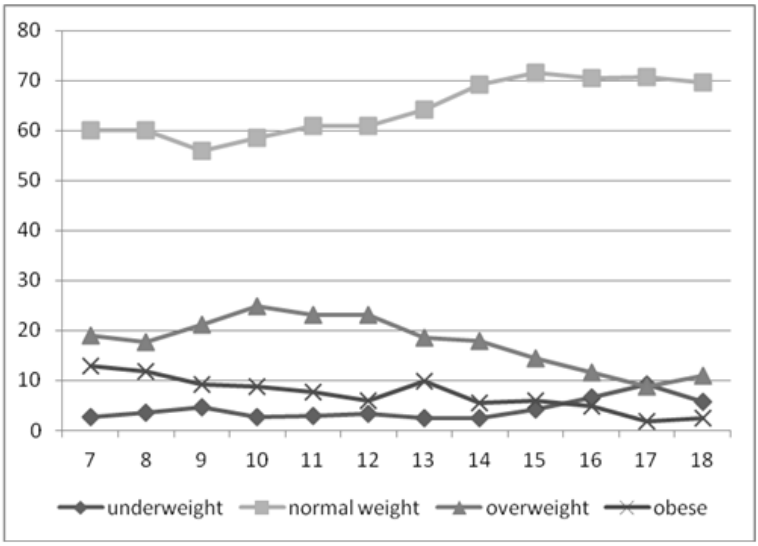

Fig. 3. Prevalence of underweight, overweight and obese in relation to age

The questionnaire was completed in full by 2393 children - 66% of children enrolled in the study, 50.6% were girls, 49.4% were boys. We did not find a strong correlation (Pearson's correlation) between BMI class and total score of the questionnaire (r_s=0.136, p=0.5), but a detailed analysis showed a stronger correlation of the two parameters that increased with age (r_s=0.358, p=0.04 for 16 to 18 years group). In scoring individual variables we observed that the strongest direct correlation was found relating BMI class to the consumption of sweets (r_s=0.536, p=0.0005) and sweetened beverages (r_s=0.243, p=0.01) and with the lowest frequency in performing physical exercise per week (r_s=0.237, p=0.0005) (fig. 4).

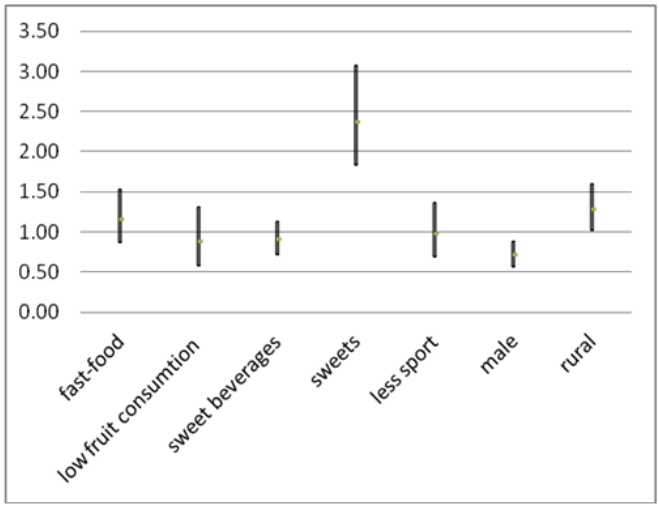

Fig. 4. Odds ratio with 95% CI for obesity associated with the different life style behaviors.

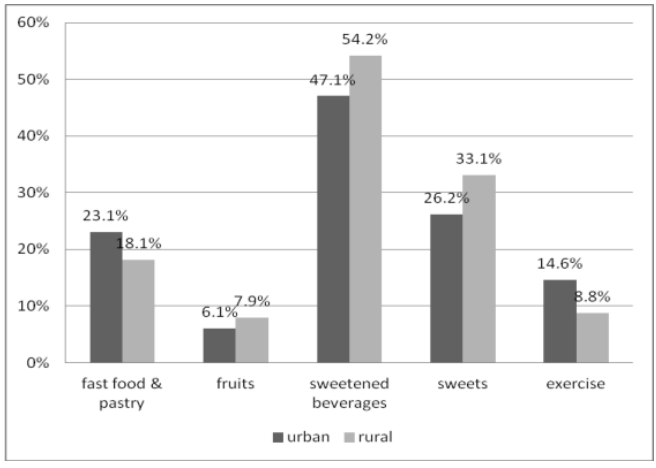

Fig. 5. The highest scores (4 and 5 = worst behavior) in urban versus rural

Further, we looked at the percentage of children who scored highest (5 on our scale) on independent variable in the questionnaire: 24% drink sweetened beverages every day, 15% eat sweets every day, while 7% eat fast food or pastry each day. Considering differences between urban and rural we found that the children who scored highest (4 and 5 = worst behavior) on the questionnaire were more prevalent in rural versus urban environment (fig. 5), but the difference was not statistically significant (p=0.83). Exception was seen in fast food and pastry consumption, which was higher for urban.

DISCUSSION

The data demonstrated a high prevalence of overweight and obesity children.

The prevalence of obesity was higher among boys versus girls and higher in rural versus urban. In Europe, for 2010, the estimates for prevalence of overweight and obesity were 38% and 10 % respectively (11). Table III shows different prevalence reports, from literature, in various countries. Even though we used the IOTF reference for BMI and some of the studies cited used different references (WHO and CDC), an indicative comparison can be made (12). Childhood obesity is becoming a global epidemic and is threatening to have reached epidemic proportions also in Romania. Alarming data generated by this study show proximate results to those from Italy.

TABLE III

Prevalence of overweight and obesity by country

Countries	Overweight %		Obesity %		Author, year, citation Growth standards
	Girls	Boys	Girls	Boys	
West Romania	16.3	20.7	5.8	9.0	Chirita Emandi A; 2012; IOTF
Greece	31.2	26.5	9.4	6.4	Tzotzas T; 2011; (13); IOTF
Canada	26.7	11.7	11.3	10.8	Twells L; 2011; (14); WHO
Italy	19.3	27.4	3.5	4.5	Cacciari E; 2006; (15); CDC
Switzerland	19.1	16.6	3.7	3.8	Zimmermann M.; 2004 ; (16); IOTF
Turkey	15.8	12.8	3.2	3.9	Turkkahraman D.2006 (17); IOTF

WHO= World Health Organization 2007;
IOTF =International Obesity Task Force 2000; CDC=Centre for Disease Control 2000

The difference in prevalence of obesity between sexes (higher in boys) may be related to maturation, growth patterns, behavioral, environmental and cultural factors (20-22), on which we have limited information relevant for the Romanian population. The increased prevalence of obesity in boys, further ads to the well known elevated short term risk for cardiovascular disease in adult men compared to women (23). The differences in prevalence of both overweight and obesity, when comparing ages of children, may be due to pubertal stage (higher prevalence in pre pubertal). Our data demonstrated higher prevalence between 8-11 years, but Tanner stage was not assessed in our study due to ethical and methodological issues. Underweight was more prevalent in girls versus boys and the prevalence increased at age 17 and 18, underlining possible cultural or peer pressure to be thin.

The higher prevalence of obesity in rural versus urban was surprising. Interestingly, children from rural environment showed that they consume more frequently sweetened beverages and sweets; and they are engaged less frequently in physical exercise. However, the difference was not statistically significant. Several studies looked at factors contributing to higher prevalence of obesity in rural areas. Weight problems in rural communities could be explained by the evolvement of farming methods, by the lack of physical activity due to socio-economic status, lower levels of medical education and interest for health

related topics, limitation of recreational facilities, less commitment time available for parents and children and high cost of activities. On the other hand, the availability of cheap, high dense energy foods could also be a cause (24, 25). Further studies are needed, in order to determine the exact causes of this issue, for Romanian socio-economic and cultural setting.

Previous researches have reported on the multivariate association of overweight with certain modifiable factors (26). We wanted to search for a correlation between BMI and some heath-risk behaviors. No significant correlation was found between obesity and the total score, but the fact that the correlations were more significant with increased age of children might raise a question about the reliability of questionnaires in young children.

Our results showed associations between obesity and consumption of sweetened beverages and sweets, in concordance with literature (27-29). It is alarming, but not surprising that in our study almost 1 in 4 children drink sweetened beverages every day. No associations between fruit consumption and obesity were observed in the current study. Other available data do not support a protective effect of fruit consumption on the risk of childhood obesity. In addition, no association between obesity and fast-food intake was proven, despite the plausible mechanisms involving increased energy uptake. We found association between reduced physical exercise and obesity, further supporting a huge number of reports (30-33). Taken together, these findings suggest that consumption of sweeten beverages, concentrated sweets and fast-food should be discouraged while physical exercise should be promoted in children in order to reduce overweight and obesity prevalence.

The gradual increase in body-weight that leads to obesity is the direct effect of a prolonged increased energy intake, which exceeds energy loss. Multiple factors can influence energy balance and, therefore, be identified as contributors to the current obesity epidemic in children, with biological, behavioral and environmental causes. Obese children are at an increased risk of developing chronic diseases, particularly diabetes mellitus and cardiovascular diseases, which can lead to the poor quality of life, an increased personal and financial burden to individuals, families, and society, and a shortened lifespan (33). Targeted interventions tailored to local circumstances are urgently needed.

It is important to take into account several limitation of the study. The geographical area for the studied population was restricted and results cannot be generalized for the country, but nevertheless, this could be the start for a national study. The age of children was rounded leading to possible minor inaccuracies regarding prevalence estimation. Dietary data in the current study were determined based on the frequency of consumption of food items without any details on the quantity consumed that could have attenuated and potentially masked certain associations.

CONCLUSIONS

The prevalence of overweight and obesity children is alarming, particularly in boys, higher in rural versus urban. Associations between obesity and consumption of sweetened beverages and sweets; and reduced physical exercise were showed. Children from rural environment showed that they consume more frequently sweetened beverages and sweets; and they are engaged less frequently in physical exer-

cise. The findings confirm the urgent need for national preventive strategy for childhood obesity and targeted interventions tailored to local circumstances.

ACKNOWLEDGEMENTS

Measurements were done by medical students, volunteers of "Save the Children", coordinators: Iulia Jurca-Simina, Ioana Alina Moaca, Laura Leahu. Authorization for implementing this study was obtained from the Timis Learning Inspectorate.

THE PREVALENCE OF ANEMIA IN PATIENTS WITH INFLAMMATORY BOWEL DISEASES IN NORTH-EASTERN ROMANIA (Abstract): Anemia is a frequent complication of inflammatory bowel diseases (IBD). The main incriminated mechanisms are the iron deficiency and the chronic inflammation. **The aim** of this study was to determine the prevalence of anemia in IBD patients and to identify the main causes. **Material and methods:** A prospective study was carried out between April 1st 2011 and April 30th 2012 on a batch of 144 IBD patients diagnosed in the Gastroenterology and Hepatology Center of Iasi. The IBD diagnosis was based on clinical, biological, endoscopic and histological criteria. The anemia diagnosis was based on the World Health Organization criteria. **Results:** Anemia was present in 40.27 % of IBD patients. The main cause identified was mixed type anemia, followed by iron deficiency and inflammation. Iron deficiency anemia was present especially in patients with ulcerative colitis with long evolution, frequent activity spurts and extended forms of diseases; an inflammatory anemia emerged mainly in patients with extended and moderate-severe forms of the diseases. **Conclusions:** Anemia remains a frequently associated pathology to the inflammatory bowel disease that requires specific management. **Keywords:** PREVALENCE, ANEMIA, IRON DEFICIENCY, INFLAMMATORY BOWEL DISEASE.

The inflammatory bowel diseases (IBD), the Crohn disease (CD) and the ulcerative colitis (UC) are polyfactorial inflammatory conditions of the digestive tube with genetic determinism, characterized by periods of activity and remission. The evolution of both UC and CD associate a frequent but underestimated complication: anemia. Diagnosis and adequate treatment of this polyfactorial complication improves the life quality in IBD patients, decreasing hospitalization length and frequency and the need of blood transfusion (1).

Two major causes of IBD anemia have been identified in the literature (1, 2): iron deficiency and chronic inflammation. Despite this, IBD anemia is most of the times polyfactorial, often the result of inflammatory anemia (characteristic to acute spurts) associated to iron deficiency anemia. Other possible mechanisms involved are: the malabsorption of vitamin B_{12} and folic acid

met only in patients with ileal involvement or extended resections at this level, drug-induced anemia (sufasalazine, thiopurine), hemolytic anemia, myelodysplastic syndrome.

Another feature is the preponderance of this condition in young segments of the population, which involves high socio-economic costs for repeated hospitalizations and absenteeism from the work place. These are arguments for the importance of diagnosing and treating anemia in IBD (3).

The aim of this study was to determine the prevalence of anemia in IBD patients hospitalized in a third centre, and to identify the main mechanisms of anemia and the main correlations between the type of anemia and the clinical-evolutional data of the IBD.

MATERIAL AND METHODS

A prospective descriptive study was carried out between the 1st of April 2011 and the 30th of April 2012, on a batch of 144 IBD patients in the Gastroenterology and Hepatology Center of Iasi. The diagnosis of the inflammatory bowel disease was set on clinical, biological, endoscopic and histological criteria.

The demographic parameters (age, gender, type of disease, duration and extension of lesions and activity) were taken into account. In order to establish the disease activity, the CDAI score was used for the Crohn disease, while the UCDAI score was employed for the UC.

The World Health Organization (4) defines anemia as the pathologic condition when Hb decreases to < 12 g/dl in women and to <13 g/dl in men. In the classification of the type of anemia, the following parameters were monitored: the Hb value, erythrocyte indexes, serum iron level, ferritin, C reactive protein (CRP) and the erythrocyte sedimentation rate (ESR).

For the iron deficiency anemia, the inclusion criteria were: low erythrocyte indexes (MCV < 78 μc), Serum Fe < 50 mg/dl, ferritin < 30 ng/dl; for inflammatory anemia: normal erythrocyte indexes (78 μc < MCV < 94 μc), ferritin >100ng/dl, CRP> 0,5mg/dl, ESR>12 mm/1h). For the mixed anemia (inflammatory + iron deficiency) the following diagnosis criteria were considered: low or normal erythrocyte indexes, 30 ng/dl < ferritin < 100 ng/dl, Serum Fe - normal or low, CRP> 0.5 mg/dl, ESR> 12 mm/1h.

The patients showing other possible causes of anemia were excluded: genital-urinary conditions in women, gastric/ hemorrhagic duodenal ulcer, hemorrhagic hemorrhoids, tumors or anemia of other hematological causes.

The data were analyzed using the *SPSS 16.0* programme. The value of p=0.05 was taken as threshold of statistic significance.

In order to test the statistical hypotheses and to compare the groups of continuous variables and, respectively, the groups of categorical variables, the repartition Student (t) and chi-square (χ^2) were used. The univariate dispersion analysis (the ANOVA test) was also used, as well as the Levene test for the analysis of the dispersion homogeneity.

RESULTS

The study included 144 IBD patients divided into two sub-groups: sub-group A: 105 patients with UC and sub-group B: 39 patients with CD. Patients were aged between 18 and 76, the average age being 44.41 years; regarding the repartition per gender and per diagnosis: 61 were women (20 with CD, 41 with UC) and 83 men (19 with CD and 64 with UC).

Subgroup A: The extension of lesions depended on the Montreal classification; thus, of the 105 patients with UC: 21% had proctitis (E1), 50.5% left colitis (E2), and 28.5% pancolitis (E3).

As far as the disease activity at enrolment into the study is concerned: 12 patients with UC (11.4%) were in clinical and biological remission, 22 presented slight activity (21%), 32 in moderate activity (30.5%), and 39 had severe activity (37.1%).

Forty patients with UC (38.09%) met the criteria for anemia: 16 patients had iron deficiency anemia, 11- inflammatory anemia and 13 - mixed anemia (iron deficiency + inflammatory) (fig. 1).

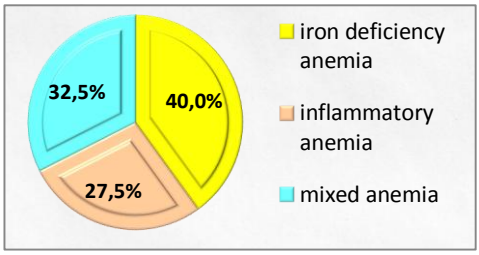

Fig. 1. Types of anemia in UC patients

Regarding the disease activity, inflammatory and mixed anemia prevailed in moderate and severe spurts. In remission, slight spurts – iron deficiency anemia prevailed (fig. 2).

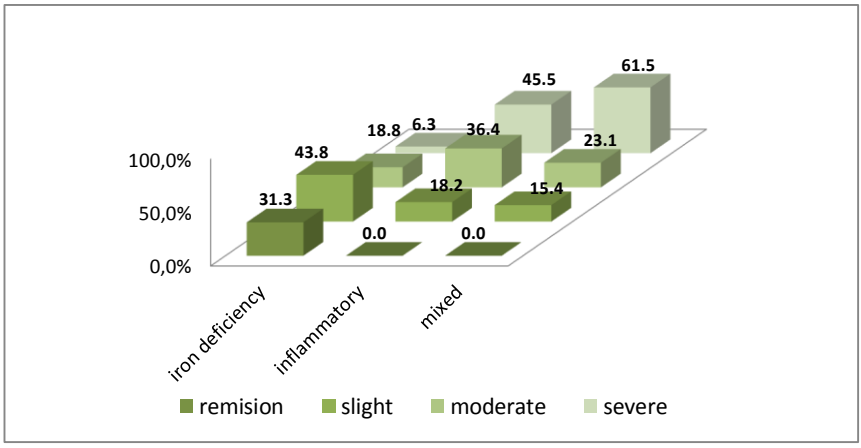

Fig. 2. Anemia type vs. UC activity form

Also, the iron deficiency anemia was found especially in patients with UC in extended forms of the disease (pancolitis, left colitis) (fig. 3) and with long evolution of the disease (5.36 years), whose history shows several activity spurts per year (3.2 spurts/ year), which led to a persistent chronic blood loss.

Subgroup B:

From the 39 patients with CD: 7.7% presented involvement of the terminal ileum (L1), 46.2% involvement of the colon (L2), 38.5% involvement of the ileum and colon (L3), 5.1% presented involvement of the upper digestive tube (L4), and 2.6% involvement of the upper digestive tube and of the terminal ileum (L1+L4).

Considering the disease activity at enrolment into the study: 12 patients (30.8%) were in clinical and biological remission, 10 presented slight activity (25.6%), 13 - moderate activity (33.3%), and 4 patients severe activity (10.3%).

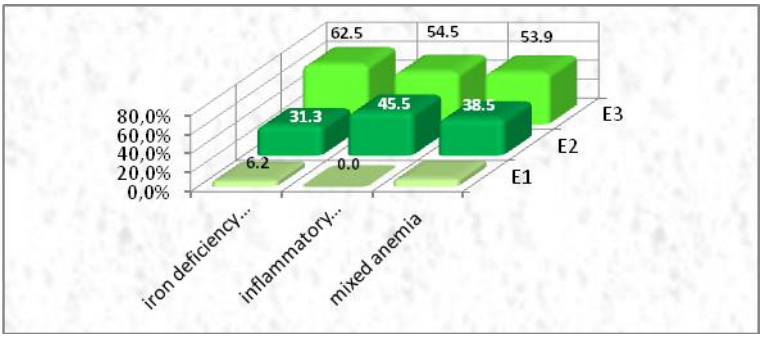

Fig. 3. Anemia type *vs.* disease localization (UC)

Eighteen (46.15%) of the 39 patients with CD had anemia: 4 patients iron deficiency anemia, 2- inflammatory anemia, 10 - mixed anemia, and 2 patients with terminal ileum resection had macrocyte anemia secondary to vitamin B_{12} and folic acid deficiency (fig. 4).

From the point of view of the disease activity, it was also noticed that in moderate and severe spurts, inflammatory and mixed anemia prevailed; in remission, slight-moderate spurts, iron deficiency anemia prevailed (fig. 5).

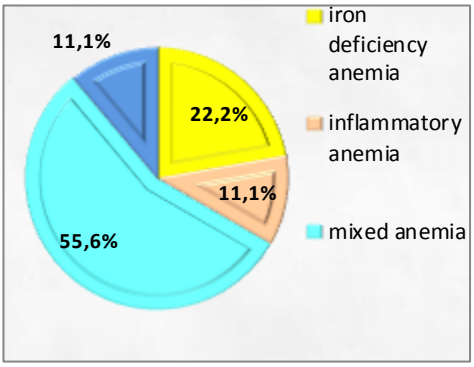

Fig. 4. Anemia types in patients with CD

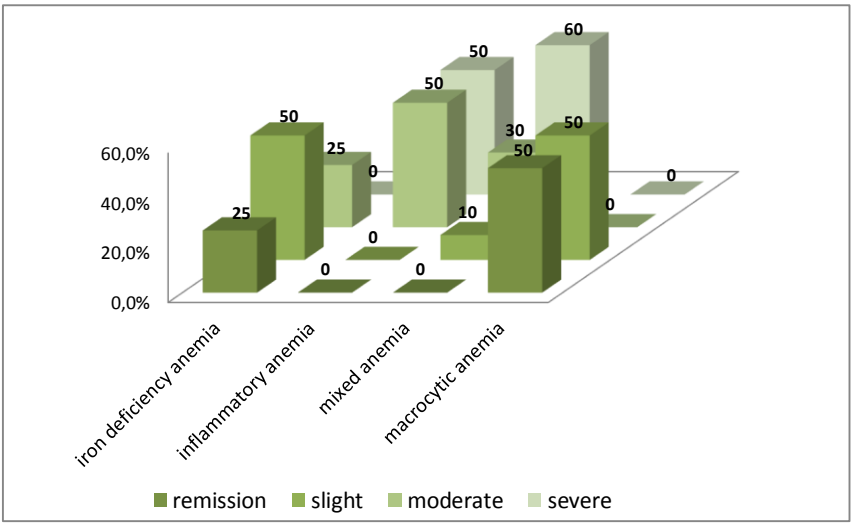

Fig. 5. Anemia type vs activity form of Crohn Disease

The comparison of the anemia cases from the two subgroups reveals the fact that anemia was more frequently found in patients with CD. Iron deficiency anemia prevailed in UC patients, while mixed anemia in patients with CD (fig. 6).

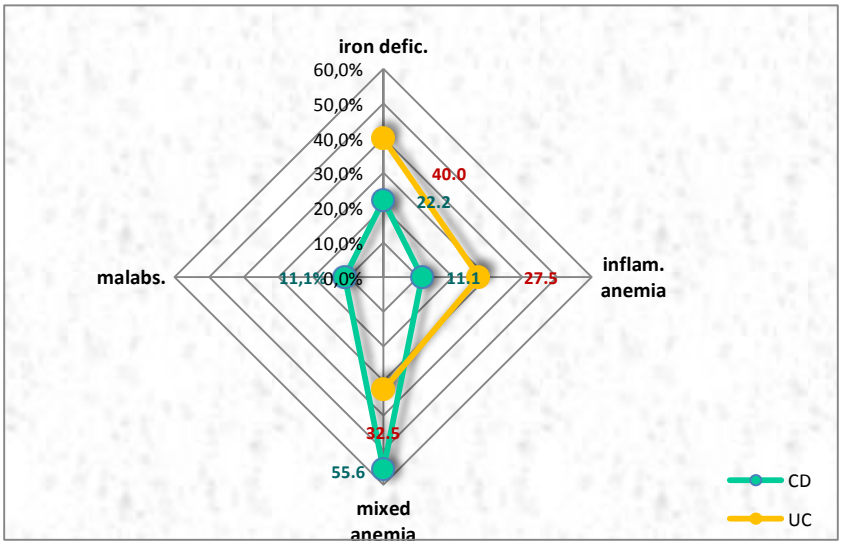

Fig. 6. Anemia type *vs.* diagnosis

TABLE I

Hematological and biochemical determinations in IBD patients with anemia

Marker	Iron deficiency anemia	Inflammatory anemia	Mixed anemia	p
Hb (g/dl)	9.81 ±1.87	11.19±1.16	10.76±2.20	**0.012**
MCV (/fl)	76.01±9.01	83.62±5.06	80.65±8.00	**0.009**
RDW (%)	15.84±2.23	14.22±2.17	14.55±1.99	**0.031**
Ferritin (ng/dl)	7.93±7.19	230.71±145.49	57.90±24.53	0.086
Serum Fe (mg/dl)	25.28±30.14	40.32±24.92	47.96±41.20	**0.001**

ESR (mm/1h)	28.67±22.952	51.45±21.205	38.48±28.853	0.164

The analysis of the hematological and biochemical values (table 1) revealed that C reactive protein was significantly high in patients with inflammatory or mixed anemia, while RDW (red blood cell distribution) was significantly high in patients with iron deficiency anemia.

DISCUSSION

There are multiple evidences as regards the increased prevalence of anemia among patients with inflammatory bowel diseases. The iron deficiency is very frequent, in approximately 60-80% of the patients, but only one third of them develop anemia (1).

The three major causes of iron deficiency in IBD are: hemorrhage at bowel level, insufficient duodenal absorption and the diet of IBD patients, which predisposes to insufficient iron input in nutrition (5-7). Anemia

prevalence is highly variable: 6% in patients treated as outpatients and, respectively, 68% in hospitalized patients (8, 9).

Studies from the literature (10-12) establish a prevalence of anemia between 19 and 40% for the hospitalized patients, the frequent causes being iron deficiency, anemia by multiple mechanisms and inflammatory anemia. Some studies assert a higher prevalence of anemia in patients with CD compared to the patients with UC.

In the studied batch, iron deficiency was present especially in patients with ulcerative colitis with long evolution and extended forms of diseases (pancolitis, left colitis), with often activity spurts that led to a persistent chronic blood loss. Inflammatory anemia emerged mainly in patients with extended and moderate-severe forms of the diseases.

A study developed in Italy by Bergamaschi et al. (13) certifies that, at the time of diagnosis of the inflammatory bowel disease, the inflammation represents the main cause of anemia, correlated with increased markers of the inflammation. Iron deficiency anemia occurs after months or years of evolution, correlated with a persistent chronic blood loss at the intestinal level and iron malabsorption.

Another study developed in Great Britain certifies that iron absorption at the level of the digestive tract of patients with IBD in remission resembles the general population, but decreases exponentially in activity spurts (14).

Although in the literature, the first mentioned cause of anemia is iron deficiency, in our study, the main cause was mixed type anemia. At study entry, most patients had moderate and severe spurts of activity, which is explained by the profile of the hospital where the study was performed. The data show a good correlation between the severity of the activity spurts, the extension of the lesions and the presence of the inflammatory anemia and the mixed anemia.

According to the study, anemia was present in more than 40% of the patients, which overlaps with the data in the specialty literature (10-12). No significant differences were noticed in the prevalence of anemia in patients with Crohn's disease compared to UC patients (46.15% *vs.* 38.09%). In the studied batch, 2 cases of macrocyte anemia were noticed in two patients with CD and resection of terminal ileum – probably due to the deficiency of folates and vitamin B_{12} induced by the lack of absorption at the ileum level.

CONCLUSIONS

In Romania, anemia represents a pathology frequently associated to inflammatory bowel diseases and calls for an adequate diagnosis and treatment.

Mixed anemia remains the main cause of anemia among hospitalized patients, followed by inflammatory anemia and iron deficiency anemia. A good correlation is noticed between the severity of the activity spurts, the extension of the lesions and the presence of inflammatory and mixed anemia. Iron deficiency anemia is noticed especially in patients with ulcerative colitis, with extended forms of the disease and often activity spurts.

NON-ALCOHOLIC FATTY LIVER DISEASE IS ASSOCIATED WITH CARDIOVASCULAR RISK FACTORS OF METABOLIC SYNDROME (Abstract): **Aim**: To evaluate the prevalence of steatosis and to assess its correlations with the classical cardiovascular (CV) risk factors, components of metabolic syndrome (MS) in a rural population. **Material and Methods**: A sample of 254 subjects was enrolled in the study. Collected data included: age, gender, complete medical history, anthropometric and blood pressure (BP) measurements. The biological evaluation included metabolic and hepatic parameters. Ultrasound evaluation of steatosis relied on the criteria of the National Health and Nutrition Examination Survey (NHANES) III. **Results**: Two thirds of the study population were obese or overweight (64.96%); 32.66% had systolic BP and 27.16% diastolic BP levels higher than normal. 38% of the subjects had abnormal fasting blood glucose levels, 14.56% having glycated hemoglobin (HbA1c) values corresponding to pre-diabetes, and 9.84% to overt diabetes; 8% had low HDL-cholesterol and 14.96% high triglycerides (Tg) levels. MS was present in 50.8% of individuals. Only 10.8% of all subjects did not have an ultrasound appearance of steatosis; 28.8% had moderate and 32% severe steatosis. There were statistically significant differences in subjects with steatosis vs. subjects without steatosis with regard to body mass index (BMI), WC, presence of MS, and BP and Tg levels, but not to ALAT, ASAT and GGT values. **Conclusions:** The important prevalence of obesity, fasting hyperglycamia, steatosis and MS shows a particularly metabolic fragile population; early diagnosis and interventional strategies are mandatory. **Key words**: METABOLIC SYNDROME, STEATOSIS, CARDIOVASCULAR RISK FACTORS

Metabolic syndrome (MS) is a cluster of interrelated risk factors for CV disease, with a rising prevalence worldwide. People with any three of the following five criteria are considered to have MS: increased WC (with ethnicity specific values); high Tg (≥150 mg/dl); low HDL-cholesterol (<40 mg/dl for males and <50 mg/dl for females); elevated BP (systolic ≥130 mmHg and/or diastolic ≥85mmHg); high fasting glucose level ≥100 mg/dl (1). MS is highly prevalent in the general population (approximately 22%), with race, gender and age-related differences. It carries a high CV morbidity and mortality, particularly in the presence of diabetes, which makes early

and correct assessment mandatory (2).

Non-alcoholic fatty liver disease (NAFLD) covers a histological spectrum of diseases which include simple steatosis and non-alcoholic steatohepatitis (NASH), occurring in the absence of significant alcohol consumption or other specific causes of hepatitis. NAFLD is in fact the most common liver disease, its prevalence being estimated at 20-30% of the general population in Western countries (3, 4).

The relationship of NAFLD with MS features has been confirmed repeatedly. Abdominal obesity, hypertension, dyslipidemia (especially high Tg and low HDL-cholesterol levels), and type 2 diabetes, MS components, are associated with insulin resistance (IR), and frequently, not only that they are also associated with NAFLD, but their coexistence within the same individual increases the likelihood of more advanced forms of liver disease (2, 5, 6). Most patients with NAFLD are hyperinsulinemic and more insulin resistant compared with healthy subjects without steatosis, and there is a near universal association between NAFLD and IR, irrespective of obesity (7). There is an independent association between liver steatosis and carotid atherosclerotic plaques and endothelial dysfunction. This relationship remains statistically significant after adjustment for risk factors of MS (3, 8). NAFLD and atherosclerosis share common molecular mediators, and NAFLD itself might play an early role in the development and progression of atherosclerosis. ALAT significantly predicts the incidence of MS and type 2 diabetes, association that remains after adjustment for a large number of risk factors (including direct measurements of insulin sensitivity and insulin secretion).

All these correlations indicate that NAFLD may be the hepatic manifestation of MS (3). The presence of multiple metabolic disorders such as diabetes mellitus, obesity, dyslipidemia, and hypertension is associated with a potentially progressive, severe liver disease (3, 9).

The aim of this study was to evaluate the prevalence of steatosis in a rural community, and to assess its relationship with the classical cardio-vascular risk factors, components of MS.

MATERIAL AND METHODS

We conducted a cross-sectional study on 254 subjects, 152 women (59.84%) and 102 men (40.15%). The mean age of the study population was 55.04±16.28 years. Subjects were randomly selected from a database of 3248 people who participated in the National Health Program (2007-2008). The site of the study was Deleni, a representative rural community in Iaşi County. Subjects were convened by their general practitioners and provided written informed consent before enrolling in the study. Ethical approval was obtained from the University Ethics Committee.

The collected data included: age, gender, complete medical history, anthropometric measurements (weight, height, WC), assessment of BP, hepatic ultrasound, and biological parameters (fasting glycemia, HbA1c, total-, HDL- and LDL-cholesterol, Tg, ALAT, ASAT, GGT). Food frequency questionnaires, including alcohol consumption, were applied to all subjects (alcohol consumption was considered significant when > 20g/day.)

Body weight and height were recorded with subjects wearing light clothes and no shoes, using standard techniques and equip-

ment. We calculated BMI as weight/height^2 (kg/m^2) and used World Health Organization (WHO) criteria to define BMI categories: underweight (≤18.5 kg/m^2), normal weight (18.5-24.9 kg/m^2), overweight (25-29.9 kg/m^2) and obesity: grade 1 - 30-34.9 kg/m^2, grade 2 - 35-39.9 kg/m^2, grade 3 ≥40 kg/m^2. WC was measured midway, between the lower rib margin and the anterior superior iliac spine, with the subject standing, at the end of a gentle expiration. Normal WC was defined as ≤80 cm in women and ≤94 cm in men. For the ultrasound evaluation of steatosis we followed the National Health and Nutrition Examination Survey (NHANES) III criteria, recording parenchymal brightness, deep beam attenuation, bright vessel walls and gallbladder walls definition; overall estimation was based on the number of ultrasound findings.

The statistically package SPSS version 16.0 for Windows (Chicago, IL, USA) was used for data analysis. A p value <0.05 was considered statistically significant. The significance of differences between continuous variables was assessed using the Student's t test and One-way ANOVA test and for categorical variables the Pearson Chi-Square test.

RESULTS

Mean BMI was 27.68±5.78 kg/m^2 (tab. I). We found that 1.96% of the study population was underweight, 33.07% normal weight, 35.83% overweight, and 29.13% obese. Two thirds of this population were obese or overweight (64.96%). As to obesity grade: 21.25% were grade 1, 5.90% - grade 2, and 1.96% - grade 3. Analyzing the WC values, it resulted that only 20.22% of men and 9.69% of women had normal WC, also meaning that the prevalence of abnormal WC values was higher in women than in men (90.27% *vs.* 79.77%, p=0.02).

TABLE I

Characteristics of the study population:

	Age (years)	Weight (kg)	Height (m)	BMI (kg/m^2)	WC men (cm)	WC women (cm)
N	254	254	254	254	89	165
Mean	55.04	72.89	1.625	27.6808	104.118	94.3636
Std. Error of Mean	1.022	0.975	0.0070	0.36279	16.6014	9.7085
Median	56.00	71.00	1.620	26.9459	103.5	95
Std. Deviation	16.288	15.540	0.1114	5.78203	16.6954	9.7380
Variance	265.291	241.503	0.012	33.432	278.738	94.8303
Minimum	21	23	0.6	16.1354	66	66
Maximum	91	126	1.9	63.8889	141	122

As to the presence of the other CV risk factors, 5.90% of the subjects already had diabetes at the time of enrolling in the study; 30.31% of subjects were known with hypertension (treated or not), with a higher prevalence in men (34.83% *vs.* 27.27% in women). Analyzing the distribution of arterial BP levels, we found that 32.66% of the subjects had systolic arterial BP and 27.16% diastolic arterial BP higher than

normal (with the preponderance of values corresponding to grade 1 hypertension – 18.11% for systolic and 19.29% for diastolic blood pressure).

With regard to the alcohol consumption, 12.5% were heavy drinkers, while 45.06% never (or almost never) drank alcohol.

The analysis of the results of biologic parameters assessment revealed that only 62% of the study population had normal fasting blood glucose levels, while the remaining 38% had levels corresponding to impaired fasting blood glucose or even diabetes. Results of HbA1c determination showed that 75.59% had normal values, 14.56% were in the range of values corresponding to pre-diabetes, and 9.84% to overt diabetes. Analyzing the lipid profile, we found that 8% of the study population presented low HDL-cholesterol, 62% high LDL-cholesterol, and 14.96% higher than normal Tg levels. As to liver tests, we noticed that 95% of the study group had normal ASAT values, while the proportions was a little lower for ALAT – 91%, and even lower for GGT – 82%. When values were abnormal, the changes were moderate, the mean values for all three markers being in the range of normal values (22.72± 14.33mg/dl for ASAT, 25.57±14.96mg/dl for ALAT and 31.66± 32.55mg/dl) (tab. II).

TABLE II

Biochemical parameters of the study population:

	Glycemia (mg/dl)	HbA1c (%)	Total cholesterol (mg/dl)	Tg (mg/dl)	HDL (mg/dl)	LDL (mg/dl)	ALAT (u/l)	ASAT (u/l)	GGT (u/l)
Mean	112.04	5.891	179.90	109.57	46.19	111.983	20.72	25.57	31.66

Minimum	57	4.9	93	39	24	42.8	2	3	5
Maximum	371	12.6	310	510	72	233.6	128	146	241

Using the new criteria for MS, the prevalence in the study population was very high (50.8%).

We found a significant correlation between ALAT and BMI, HDL-cholesterol, Tg, fasting blood glucose, and HbA1c, and also between WC and HDL levels. The correlation was very strong for ALAT with WC and for Tg with WC, fasting blood glucose and HbA1c.

Of the initial 254 patients, 222 underwent hepatic ultrasound for assessing the presence of steatosis. The results revealed that only 10.8% of all patients did not have an ultrasound appearance of steatosis; 28.4% had intermediate, 28.8% moderate and 32% severe steatosis. No gender or age-related differences were found.

When reported to BMI, the prevalence of steatosis was 75% in BMI normal sub-

jects, 94.3% in overweight, and 97% in obese persons, with similar proportion if WC was used as criterion (statistically significant differences, p<0.001 for BMI and p=0.032 for WC). In the non-hypertensive population 85.2% were found to have steatosis *vs.* 93.5% in the hypertensive group (p=0.048). In the presence of MS, the prevalence of steatosis was 92.4%, against 85.6% in those without MS (p>0.05). When we analyzed the data on the severity of steatosis – no/intermediate *vs.* moderate/severe steatosis, the prevalence of moderate or severe steatosis in normal weight subjects was 41.2%, increasing to 84.8% in obese and 67.8% if the MS was present (versus 54.8% in persons without MS). These are statistically significant differences - p<0.001 for BMI and WC categories and p=0.023 for MS (tab. III). The differences are not significant for the previous diagnosis of hypertension, but systolic and diastolic BP were statistically significant higher in the presence of steatosis (regardless of its severity) - p=0.003, p=0.006 respectively.

TABLE III

Prevalence of steatosis in the study population:

Steatosis															
		No/I (%)	M/S (%)			No/I (%)	M/S (%)			No/I (%)	M/S (%)			No/I (%)	M/S (%)
BMI	N	7	41.2	WC	N	79.5	35.9	HT	-	85.2	54.8	MS	-	85.6	52.9
	OW	94.3	58		AO	91.3	66.1		+	93.5	67.3		+	92.4	67.7
	Ob	97	84,8												
p		<0.001	<0.001			0.032	<0.001			0.048	0.056			0.104	0.023

I – intermediate steatosis; M – moderate steatosis; S – severe steatosis; No – normal;
OW – overweight; Ob – obese; AO – abdominal obesity; HT – hypertension (anterior diagnosis).

Analyzing the relationship between steatosis (ultrasound assessment) and biological (metabolic and hepatic) markers, we observed that ALAT, ASAT, GGT and HbA1c values did not differ in the presence of steatosis. On the other hand, BMI, WC and Tg values were significantly higher in the presence of steatosis, regardless of its severity (p<0.001). As to the severity of steatosis, age was significantly higher in the presence of moderate or severe steatosis (p<0.001).

DISCUSSION

Despite limited accuracy of NAFLD diagnosis (liver biopsy is still the gold standard), many studies suggest that 20-30% of individuals in Western countries have NAFLD. The prevalence increases from 16.5% in lean persons to 75% in obese persons (3). A study in Japanese population showed that the prevalence of NAFLD increased from 43% in individuals with impaired fasting glucose to 62% in individuals with type 2 diabetes mellitus (3).

NAFLD may represent the majority of unexplained cases of aminotrasferase elevation (10). A recent survey indicates that NAFLD may account for approximately 80% of the cases with elevated liver enzyme levels in the American population, and that 1 in 4 American adults actually

have NAFLD. Similar data have been obtained in the Japanese and Italian populations (3, 10). On the other hand, liver enzyme levels do not reliably correlate with liver histology, the full range of disease may be seen in patients who have normal transaminase levels (normal values being present in up to 78% of patients at any time) (11). In our study, we found no association between the values of liver tests and the prevalence of ultrasound steatosis. Abnormal liver enzyme levels were seen in 5% of the population for ASAT, 9% for ALAT and 12% for GGT; surprisingly, steatosis was found in 89.2% of the subjects, with 50.8% having moderate or severe forms. This observation demanded further investigation of two possibilities – either there was an error in data collection or analysing, or indeed this population had an extremely high prevalence of fatty liver. We checked for possible sources of error without finding any - for example, the subjects with known liver diseases were not enrolled in the study, and all ultrasounds were performed by the same experienced specialist. Hence, we concluded that we were faced with a population with a worrying prevalence of steatosis.

There are different suggestions regarding the level of alcohol consumption that can reliably distinguish between alcoholic fatty liver and NAFLD. Many centers accept a maximum allowable level of alcohol intake for definition of NAFLD of 140 g/week in men and 70 g/week in women (7). In our study significant alcohol consumption was recorded in 12.5% of study population, which cannot be a valid explanation for such a high prevalence of steatosis. Another possible etiologic factor is dyslipidemia and, indeed, we observed that 62% of our study population had high LDL-cholesterol level and 14.96% had hypertriglyceridemia; furthermore, subjects with steatosis had statistically significant higher Tg levels than subjects without steatosis. In addition, 14.56% of subjects had HbA1c values in the range corresponding to pre-diabetes, and 9.84% corresponding to overt diabetes, prevalence higher than any prevalence reported in the literature and than the prevalence of diabetes previously diagnosed in this population – 5.9%. All these findings suggest that the etiology of steatosis in this population is more likely metabolic.

It has been suggested that 90% of individuals with NAFLD have at least one risk factor for MS, and 33% have all the features of MS. MS is not an absolute risk indicator, because it does not include many of the factors of absolute CV risk - for example, age, sex, cigarette smoking, and LDL-cholesterol levels. Even in these conditions, it was found that patients presenting MS have twice the risk of developing CVD over the next 5 to 10 years compared to individuals without MS, and a 5-fold increase in the risk for type 2 diabetes (1).

The biological mechanisms by which NAFLD contributes to higher risk for CV disease, independent of other prognostic factors, are not fully understood. It is possible that NAFLD, in its more advanced forms, acts as a stimulus for further increased whole-body IR and dyslipidemia, leading to accelerated atherosclerosis (12). This hypothesis is also partly validated by few prospective studies demonstrating that raised liver enzymes independently predict the development of MS, and that ALAT values and ASAT/ALAT ratio might predict the onset of fasting hyperglycemia, independent of obesity (5). The presence of

multiple metabolic disorders such as diabetes, obesity, dyslipidemia, and hypertension is associated with a potentially progressive, severe liver disease (9). Hsiao et al. demonstrated that the presence of severe fatty liver correlated significantly with the prevalence and degree of hypertension, abnormal glucose and Tg metabolism (13). In our study, the percentage of subjects with steatosis, regardless of its severity, was not significantly higher in hypertensive patients, but the values of measured BP, both systolic and diastolic were significantly higher in people with steatosis.

Another surprising result regards the prevalence of the MS in our population – 50.8%, approximately twice the "admitted" prevalence of MS in general population. This observation becomes less surprising when almost two thirds of the population is overweight or obese, as shown not only by our data (64.96%), but also by a previous study, which described the preponderance of overweight and "moderate" obesity (14). The presence of MS strongly correlates with the presence of steatosis; NAFLD and MS share multiple features and generate an important CV risk, which leads to the logic deduction that they are the expression of the same dysfunction – identified as IR. As MS includes a large spectrum of metabolic disorders, it is reasonable to include NAFLD under this big "umbrella". Considering the strong clinical impact of these disorders, an early diagnosis is mandatory; the detection of steatosis should stimulate for the screening of the other MS components and *vice versa*. NAFLD should be considered part of a multi-organ system derangement in insulin sensitivity, which would explain why it is so closely linked with diabetes and MS and is an important risk factor for coronary heart disease (8).

CONCLUSIONS

In our study population we found an impressive prevalence of obesity, diabetes and pre-diabetes, and MS. In addition, 89.2% of the study population presented steatosis, 50.8% with moderate or severe steatosis. BMI, WC, BP and Tg levels were significantly higher in the presence of steatosis, regardless of its severity ($p<0.01$); between the prevalence of steatosis and the presence of MS there was a significant relationship ($p<0.05$).

Due to this cluster of metabolic and CV risk factors, we can assert that we are faced with a particularly metabolic fragile population, and that immediate dedicated interventional strategies are highly necessary for this population.

NEWS

PARTICULAR BRAIN CENTERS ACTIVATED DURING HUMAN CONSCIOUS STATE

A study by Dresler and co. investigated which centers of the brain become active when we are aware of ourselves, the so-called state of "metaconsciousness" during lucid dreaming. The purpose of the study was to evaluate the neural correlates of lucid dreaming, using parallel EEG/fMRI recordings of night sleep in four experienced lucid dreamers. The study showed that during lucid dreaming the bilateral precuneus, cuneus, parietal lobules, and prefrontal and occipito-temporal cortices were strongly activated as compared with non-lucid REM sleep. In conclusion, lucid dreaming was associated with a reactivation of areas which are normally deactivated during REM sleep. This pattern of activity can explain the recovery of reflective cognitive capabilities that are the hallmark of lucid dreaming (Dresler M; Wehrle R; Spoormaker V et al. Neural correlates of dream lucidity obtained from contrasting lucid versus non-lucid REM sleep: a combined EEG/fMRI case study. *SLEEP* 2012; 35(7):1017–1020).

PROSPECTIVE STUDY OF THE EFFICIENCY AND SAFETY OF ADALIMUMAB IN TREATMENT OF ACTIVE ESTABLISHED RHEUMATOID ARTHRITIS (Abstract): Rheumatoid arthritis (RA) is a systemic autoimmune disease characterised by synovial pannus formation leading to cartilage destruction, bone erosion, and disability. **Aim:** To evaluate the efficiency and safety of adalimumab (ADA) in association with one or more classic remissive drugs in active established RA. **Material and methods**: Prospective observational 12 months study in 33 consecutive active RA treated with ADA. Patients were assessed according to a complex protocol including both individual parameters (clinical, biological) and composite disease activity scores (DAS28, CDAI, SDAI), while response to therapy was evaluated based on EULAR and ACR response criteria. **Results**: Statistical significant improvement has been demonstrated in all patients under ADA ($p<0.05$); after 3 months of treatment 51.5% RA fulfilled ACR20, 39.3% ACR50 and 9% ACR70 criteria; after 6 months of treatment 66.6% of patients and 33.3% fulfilled ACR20 and, respectively, ACR50 criteria. Moreover, 30.3% of all patients had good response after 6 months, 66.6% moderate response and only 3.03% displayed no response in the same period. 24.2% and 45.4% of RA achieved remission (DAS28$\leq$2.6) after 9 and 12 months of ADA, while 39.3% and 21.2% had moderate activity. Rate and type of adverse events demonstrated the safety and good tolerance of ADA. **Conclusions**: Our data support the efficacy and safety of ADA in active established RA in the settings of the real-life clinical practice. **Key words**: RHEUMATOID ARTHRITIS, ADALIMUMAB, REMISSION, LOW DISEASE ACTIVITY

Poliartrita reumatoidă (PR) este o boală imuno-inflamatorie cronică, progresivă, caracterizată prin sinovită şi afectare multisistemică, cu evoluție spre distrucție articulară ireversibilă, cu dizabilitate funcțională majoră şi risc de mortalitate precoce, îndeosebi prin afectare cardio-vasculară.

Tratamentul PR a înregistrat schimbări majore ca rezultat al unor clarificări privind mecanismele patogenice şi țintele terapeutice. Astfel, este acceptat faptul că *tumor necrosis factor alpha* (TNF-α) joacă un rol major în evenimentele patogenice esențiale ale bolii, respectiv medierea sinovitei, degradarea matricei cartilaginoase şi eroziunile osoase; inhibarea efectelor sale prin

intermediul adalimumab-ului (ADA), un anticorp monoclonal uman recombinat tip IgG1, constituie una din opțiunile terapeutice moderne în PR (1,2,3). Studiile referitoare la eficiența și siguranța tratamentului cu ADA în PR au evidențiat că, ADA reduce simptomele și semnele bolii, îmbunătățește semnificativ funcția fizică și calitatea vieții, reduce și chiar inhibă distrucția articulară (4,5). Datele obținute, din medicina bazată pe dovezi, sugerează că administrarea pe termen lung a ADA este asociată cu eficiență susținută și este, în general, sigură și bine tolerată (6,7,8).

Studiul nostru a avut ca obiective evaluarea eficienței și siguranței tratamentului cu ADA în combinație cu cel puțin un remisiv clasic, în formele active de PR aflate în stadiu avansat.

MATERIAL ŞI METODE

Am efectuat un studiu prospectiv, în intervalul 2009-2010, incluzând 33 dintr-un lot de 38 pacienți cu PR activă, fără răspuns la remisivele clasice, cu indicație de terapie biologică anti-TNFα (ADA). Cazurile au fost selectate utilizând criteriile de includere stabilite în recomandările Comisiei Naționale de Reumatologie (9): diagnostic cert de PR (criteriile Colegiului American de Reumatologie 1987, revizuite); boală severă, în ciuda tratamentului administrat, cu minim 5 articulații cu sinovită activă și cel puțin două din următoarele: redoare matinală (RM)≥60 minute, viteza de sedimentare a hematiilor (VS.H) ≥ 28 mm/1h, proteina C reactivă (CRP) ≥ 20 mg/l; lipsă de răspuns după administrarea a cel puțin două remisive clasice pe un interval de minim 12 săptămâni fiecare.

Informațiile au fost obținute utilizând o fișă de evaluare care a inclus: (i) aspecte demografice, (ii) parametri clinici individuali: număr de articulații dureroase (NAD) și tumefiate (NAT), redoarea matinală, evaluarea globală a bolii de către pacient (EGP) și medic (EGM), evaluarea durerii de către pacient (EDP), (iii) parametri biologici inflamatori și imunologici (iv) parametri funcționali (*Health Assessment Questionnaire Disability Index*, HAQ-DI), precum și (v) scoruri de evaluare a activității PR: *Disease Activity Score* (DAS28), *Clinical Disease Activity Index* (CDAI) și *Simplified Disease Activity Index* (SDAI).

Răspunsul terapeutic a fost evaluat conform criteriilor EULAR și ACR, definite prin: (i) EULAR: *bun* dacă se obține îmbunătățire a DAS28 cu peste 1,2 puncte și un DAS28 final < 3,2; *moderat* pentru o îmbunătățire a DAS28 între 0,6 și 1,2 puncte și scor DAS28 în intervalul 3,2-5,1; *absent* pentru o îmbunătățire DAS28 ≤ 0.6 sau un scor DAS28 final > 5,1; (ii) ACR20, ACR50, ACR70: îmbunătățire de 20%, 50%, 70% în NAD, NAT și în cel puțin trei din următoarele: RM, EDP, EGP, EGM, HAQ-DI și VSH și/sau CRP) (10,11). Protocolul a cuprins, de asemenea, efectuarea a 5 vizite de studiu la intervale de 3 luni, cu evaluarea medicației concomitente și a efectelor adverse legate, în special, de ADA. Cercetările noastre s-au realizat în Spitalul Clinic de Recuperare Iași, cu acordul Comitetului de Etică, iar pacienții au semnat formularul de consimțământ informat înaintea începerii studiului.

REZULTATE

1. Caracteristicele lotului de pacienți. Majoritatea pacienților incluși au fost de sex feminin (87,9%), cu vârsta medie 53,64±11,9 ani și durata medie a bolii de 10,2±5,8 ani. Inițial, toți pacienții au avut o formă de boală activă (media DAS28-VSH 7,46±0,44), cu impact funcțional moderat (media HAQ-DI 2,03±0,33) (tab.I).

TABELUL I

Caracteristicile demografice şi cele legate de boală ale lotului de pacienți

vârsta (ani)	53.64±11.93 (33-71)
sex	
feminin	29 (87.9%)
masculin	4 (12.1%)
durata bolii	
≤ 5 ani	15 (45.5%)
5-10 ani	8 (24.2%)
≥ 10 ani	10 (30.3%)
stadiul bolii	
I/II	9 (27.3%)
III/IV	24 (72.7%)

Ac anti-CCP u/ml)	114.36 (3-526)

Legendă: MTX (metotrexat); LEF (leflunomid); HCQ (hidroxicloroquine); SSZ (salazopirină); NAD (număr articulații dureroase); NAT (număr articulații tumefiate); RM (redoare matinală); EDP (evaluarea durerii pacient); EGP (evaluarea globală pacient); EGM (evaluarea globală medic); DAS28 (*Disease Activity Score 28*); CDAI (*Clinical Disease Activity Index*); SDAI (*Simplified Disease Activity Index*); HAQ (*Health Assessment Questionnaire Disability Index*); *VS*.H (viteza de sedimentare a hematiilor); CRP (proteina C reactivă); FR (factor reumatoid); Ac anti-CCP (anticorpi antipeptide ciclice citrulinate).

2. Evoluția parametrilor clinico-biologici. După trei luni, media NAD şi NAT a scăzut de la 18,15±3,01, respectiv 11,66±2,52, la 7,81±1,44, respectiv 3,84± 1,0 (p<0,001), cu rezultate similare la şase (4,51±1,67; 1,30±0,88), nouă (3,03±1,35; 0,54±0,66) şi 12 luni de tratament (2,15± 1,25; 0,30±0,63). Scădere semnificativă (p<0,001), rapidă în primele şase şi lentă în ultimele şase luni, s-a înregistrat şi pentru ceilalți parametrii individuali (fig. 1a). S-a observat o scădere precoce, semnificativă, a reactanților de fază acută, obținându-se valori apropiate de intervalul de normalitate după primele trei luni, şi anume: media VSH a scăzut de la 68,57±29,2 la 20,81± 5,19, iar media CRP a scăzut de la 36,26± 19,51 la 17,15±6,58 .

3. Evoluția indicilor de activitate şi dizabilitate a bolii. După trei luni, media DAS28-VSH a scăzut de la 7,46±0,44 la 4,70±0,30 (p<0,001), scădere ce s-a menținut şi după şase (3,61±0,40), nouă (3,11±0,51) şi 12 luni (2,80±0,55). Scădere semnificativă (p<0,001) s-a înregistrat şi pentru alți indici de activitate a bolii (CDAI, SDAI) (fig. 1b). După trei luni, media scorului HAQ-DI a scăzut cu 0,6 unități, de la 2,03±0,33 la 1,45±0,34, scădere observată şi după şase (1,13±0,37), nouă (0,95±0,42) şi 12 luni (0,83±0,46).

4. Evaluarea răspunsului terapeutic. După trei luni, 90,9% pacienți au prezentat un răspuns moderat; 3,03% unul bun, în timp ce 6% nu au înregistrat rezultate terapeutice; după şase luni, 30,3% au prezentat răspuns bun, 66,6% unul moderat şi 3% nu au avut modificări terapeutice. După nouă, respectiv 12 luni, 24,2%, respectiv 45,4% cazuri, erau în remisiune (DAS28≤2,6), iar 36,3%, respectiv 30,3%, prezentau activitate joasă (DAS28≤3,2). După trei luni, 51,5% au îndeplinit criteriul ACR20, 39,3% ACR50 şi 9%, ACR70, iar după şase luni, 66,6% au înregistrat criteriul ACR20 şi 33,3% ACR50. Pacienții care nu au avut răspuns bun sau moderat, după trei şi şase luni de tratament, au înregistrat criteriul ACR20.

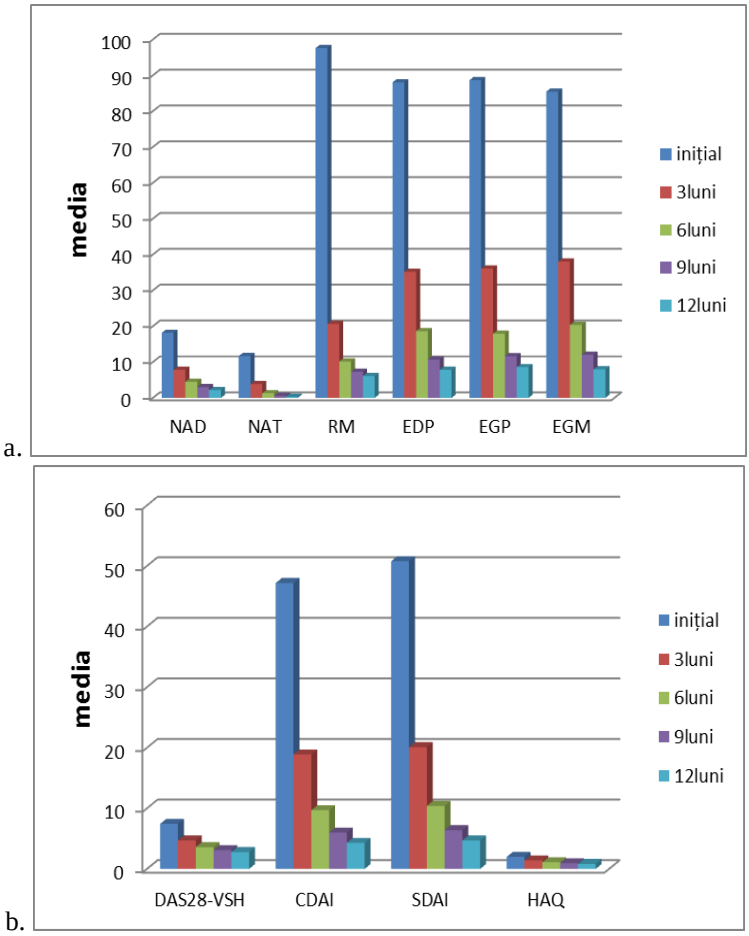

Fig. 1. Evoluția parametrilor clinici (a) şi a scorurilor de activitate a bolii (b)

5. Terapia asociată cu corticosteroizi. Din lotul de bolnavi cu PR, 33,3% au urmat tratament cu ADA asociat cu remisive clasice fără CS; 66,7% au primit CS în doză joasă (≤10mg/zi prednison). Inițial, media DAS28-VSH reflecta o boală mai activă la cei cu CS (7,36±0,21 *vs.* 7,17±0,19; p= 0,0001). În ciuda dozei de CS, diferențele în DAS28-VSH între cele două grupuri, după trei şi şase luni, au fost semnificative statistic (4,56±0.18 *vs.* 4,45±0,16; p=0,022 şi 3,46±0,28 *vs.* 3,10±0,21; *p=0,*0001), deşi comparațiile longitudinale au arătat o îmbunătățire în ambele grupuri (p<0,05). Rata celor cu răspuns bun a fost similară în cele două grupuri, după şase şi nouă luni (18,5% *vs.*11,8%; p=0,302 şi 34,7% *vs.* 25,8%; p=0,251), dar diferență semnificativă statistic (p<0,05) s-a înregistrat după 12 luni, cu un număr mai mare de pacienți cu răspuns bun la cei fără CS asociat (47,3% *vs.* 28,4%; p=0,01).

6. Evaluarea efectelor adverse. Administrarea ADA în combinație cu minim un remisiv clasic a fost bine tolerată. Nu s-au înregistrat efecte adverse grave sau severe,

ameninţătoare de viaţă; 11 pacienţi (33,3%) au prezentat efecte adverse clasificate ca reacţie uşoară la locul injecţiei. Infecţiile au survenit la 9 pacienţi (27,2%), la nivelul tractului respirator superior şi urinar inferior, fiind implicaţi *Escherichia coli*, *Proteus* şi *Klebsiella pneumoniae*. Nici un pacient nu a prezentat reactivarea tuberculozei latente, deşi unii pacienţi erau cunoscuţi cu test Quantiferon pozitiv. Pe durata studiului nu au fost înregistrate cazuri de infecţii oportuniste, neoplazie sau fenomene autoimune.

DISCUŢII

Am efectuat un studiu observaţional, prospectiv, proiectat să evalueze eficienţa şi siguranţa tratamentului cu ADA în asociere cu minim un remisiv clasic în formele active de PR aflate în stadiul avansat. Toţi parametrii clinico-biologici şi compoziţi evaluaţi au avut iniţial valori crescute, indicând o activitate crescută a PR şi impact funcţional moderat. Asocierea tratamentului cu ADA a dus la o îmbunătăţire rapidă şi susţinută în activitatea bolii şi afectarea funcţională. Astfel, s-a înregistrat o scădere precoce, semnificativă statistic, a tuturor parametrilor individuali şi compoziţi, precum şi a celor inflamatori, scădere ce s-a menţinut pe tot parcursul studiului. Îmbunătăţirea în DAS28-VSH a fost semnificativ mai mare în primele trei luni de tratament de la iniţierea terapiei comparativ cu următoarele nouă luni. După şase şi nouă luni de tratament, rata celor cu răspuns bun a fost similară în cele două grupuri (fără şi cu CS asociat), dar diferenţă semnificativă statistic s-a înregistrat după 12 luni, cu un număr mai mare de pacienţi cu răspuns bun în grupul fără CS, ceea ce arată că asocierea CS nu îmbunătăţeşte evoluţia bolii. O ameliorare importantă clinic a fost observată în primele trei luni, ceea ce vine în susţinerea datelor din literatură că, asocierea ADA la tratamentul cu remisive clasice îmbunătăţeşte capacitatea funcţională şi scade dizabilitatea. ADA asociat remisivelor clasice a fost bine tolerat, toţi pacienţii completând cele 12 luni de tratament. Majoritatea efectelor adverse raportate au fost uşoare, profilul de siguranţă al ADA fiind similar celui raportat în trialurile clinice (5,6,7,12).

CONCLUZII

Rezultatele acestui studiu demonstrează că tratamentul cu ADA în PR activă este eficient, aspect susţinut de reducerea semnificativă statistic a parametrilor clinico-biologici individuali şi compoziţi ai bolii, fiind asociată cu îmbunătăţirea funcţiei fizice şi calităţii vieţii pacienţilor. Profilul de siguranţă al ADA observat a fost comparabil cu cel din studiile anterioare. Studiul susţine utilizarea ADA în managementul pacienţilor cu forme active de PR aflate în stadiul avansat, fără răspuns adecvat la remisivele clasice, în asociere sau nu cu CS în doză joasă.

NOUTĂȚI

INHIBITORUL DE PROTEAZĂ BOWMAN-BIRK EXTRAS DIN SEMINȚELE DE SOIA

Inhibitorii de proteaze au rol protector împotriva microorganismelor patogene. Principalii inhibitori de proteaze din semințele de soia sunt inhibitorul de tripsină Kunitz (KTI) şi inhibitorul de protează Bowman-Birk (BBI). Semințele de soia incubate în apă caldă eliberează cantități mari de proteine în mediu. Analiza electroforetică a relevat predominanța globulinei 7S, a inhibitorului de protează Bowman-Birk, inhibitorului de tripsină Kunitz, peroxidazei, α-galactozidozei. Exsudatul obținut în urma incubării semințelor de soia în apă caldă a inhibat creşterea celulelor umane ale cancerului de sân MCF-7. Deoarece semințele de soia imersate în apă caldă eliberează cantități mari de BBI enzimatic activ, metoda poate fi utilizată drept o alternativă mai simplă pentru prepararea concentratului de BBI folosit ca agent chemoprotector în cancer. (Palavalli MH, Natarajan SS, Wang TT, Krishnan HB. Imbibition of soybean seeds in warm water results in the release of copious amounts of Bowman-Birk protease inhibitor, a putative anticarcinogenic agent. *J Agric Food Chem*. 2012;60(12):3135-43.

A PROSPECTIVE STUDY OF PRE-ILLNESS DIET IN NEWLY DIAGNOSED PATIENTS WITH CROHN'S DISEASE

Margarita Octoratou[1], E. Merikas[1], G. Malgarinos[1], C. Stanciu[2], J. K. Triantafillidis[1]
"Saint Panteleimon" General State Hospital, Nicea, Greece
Center for Inflammatory Bowel Disease,
1. Department of Gastroenterology
University of Medicine and Pharmacy "Grigore T. Popa" - Iasi, Romania
2. School of Medicine

A PROSPECTIVE STUDY OF PRE-ILLNESS DIET IN NEWLY DIAGNOSED PATIENTS WITH CROHN'S DISEASE (Abstract): **Background:** Environmental factors, including diet, seem to participate in the etiology of inflammatory bowel disease. The kind of dietetic habits before the appearance of the illness in patients with Crohn's disease (CD) has not been studied extensively. **Aim:** To prospectively assess the kind of food consumption in patients with CD exactly at the time of diagnosis and to identify dietary constituents as risk factors for development of CD. **Patients - Methods**: Twenty eight patients with a newly established diagnosis of CD (2-4 weeks), (12 men and 16 women), 30 patients with previously (between 2 – 11 years) established diagnosis of CD (14 men and 16 women) and 38 age- and sex-matched healthy controls (16 men and 22 women) were included in the study. Dietary intake was assessed by means of special questionnaire. **Results**: Comparisons between controls and newly diagnosed patients showed that increased consumption of milk and yogurt *(P=0.042),* fruits *(P=0.0001),* citrus *(P=0.0001),* vegetables *(P=0.0001),* carrots *(P=0.0001),* legumes *(P=0.036),* fish and selfish *(P=0.001),* honey *(P=0.003),* and nuts *(P=0.038),* was associated with decreased risk for CD. On the other hand, significantly increased intake of fat *(P=0.041),* olive oil *(P=0.038),* margarine *(P=0.038),* sugar *(P=0.02),* alcohol drinks *(P=0.009),* fried food *(P=0.0001),* and pasta *(P=0.0001),* was noticed on recently diagnosed patients in comparison with the healthy control group. On logistic regression analysis foods remaining statistically significant were: margarine, pasta, fried foods, fat, olives, sugar (increased risk), and yogurt, honey, fruits, nuts, fish, and citrus fruits (decreased risk). Newly diagnosed patients were significantly overweighed (64%) compared to healthy people (26%) and old patients (7%). **Conclusion**: Significant differences in many kinds of food between newly diagnosed patients with CD, patients with established CD and normal people certainly exist. Our results suggest that specific dietary patterns could be associated with higher or lower risks for CD in adults. However, whether these dietary factors are important for the development of CD or modulate the effect of other environmental factors is unknown. **Key words**: CROHN'S DISEASE, INFLAMMATORY BOWEL DISEASE, DIET, ETIOLOGY, PRE-ILLNESS DIET.

During the last years significant changes in the epidemiology of inflammatory bowel disease (IBD) were observed. The incidence of IBD and especially of Crohn's disease (CD) increased significantly in most countries. Today, in the European

countries the North to South gradient does not yet exist, while the West to East gradient is diminishing (1).

Since the increase in the incidence of CD could not be explained only by genetic or immunological factors alone, it was considered to relate with lifestyle changes. Diet, has been suggested to be one of environmental factors that interacting with genetic and immunological factors could lead to the development of CD (2).

Overall fat intake and high intakes of mono-unsaturated and poly-unsaturated fatty acids are considered to be risk factors for the development of IBD (3, 4). While clinical evidence suggests that long-chain triacylglycerols and probably ω-6 fatty acids might play a role in CD pathogenesis, polyunsaturated fatty acids (PUFAs) have emerged to modulate both inflammation and immunity processes (5) and n-3 PUFAs are examined to act as potential therapeutic agents (6). There is evidence that a-tocopherol and epigallocatechin gallate (ECGC) decrease IL-1, an important pro-inflammatory mediator crucial in IBD pathogenesis (7). Nutrigenomics is a new promising field, with a recent focus on CD related genes and nutrient interaction, such as those involving the receptor-mediated cytokine induction and autophagocytosis (8).

Other foods found in epidemiological studies to influence the expression of IBD include refined sugar, fruits, vegetables and fiber (9).

However, there is skepticism concerning the role of diet as a risk factor since it is not yet clear whether the differences in consumption are the cause or the result of the disease (10, 11). Moreover, mnemonic bias is an important problem when pre-illness diet is evaluated. Studies dealing with pre-illness diet habits of patients with CD are relatively few and their results are inconclusive (12-15).

The aim of this study was to assess the pre-illness food consumption of recently diagnosed patients with CD in comparison with healthy controls. This could indicate a possible involvement of pre-illness diet to the pathogenesis of the disease. A second comparison with the food consumption of patients with established diagnosis could possibly clear up the hypothesis that differences in consumption are more than the results of the disease.

PATIENTS AND METHODS

Population

The study was conducted at our Center for Inflammatory Bowel Disease at "Saint Panteleimon" General Hospital Nicea, Greece. The sample (non-probability convenience sampling) consisted of 96 subjects, divided into three groups. The first one consisted of 28 recently diagnosed (2-4 weeks) patients with CD (12 men and 16 women) comprising the group of "new" patients. A dietician (the first of the authors) interviewed all patients immediately after confirmation of diagnosis. The second group consisted of 30 patients with previously (between 2-11 years) established diagnosis of CD (14 men and 16 women) (group of "old" patients) and the third group consisted of 38 age and sex-matched healthy controls (16 men and 22 women).

Questionnaire

In order to collect the data a three-part questionnaire was employed. The first part included information of demographic data, height, weight and age, lifetime smoking habits, other health problems, medication and stress level (self-estimation). The main part consisted of a semi-quantitative Food

Frequency Questionnaire (FFQ) that was designed after 1) studying the relevant bibliography and consulting the original Willet's FFQ, 2) studying the methodology of former European, USA and Japan case-control studies, and 3) taking under consideration the food list applied by the EPIC study (in order to conclude regional food consumption).

The FFQ included 11 groups of food (diary products, fruit, vegetables, grains, legumes, meat, cooked meals, various food, sweets and sweeteners, fats and oils, drinks) which comprised in total 122 food items including ethnic foods and drinks. The consumption of each food item was measured by the use of an interval scale from 1 to 9, with category "1" corresponding to consumption "few times a year or at al", and category "9" corresponding to consumption "7+times a day". "Steady/ fixed quantities ("egeg one cup") or "natural" quantities ("egeg one apple") measured the size of portion.

Subjects were asked to describe the nutritional habits concerning the last two years. They also asked to describe for each food group if any changes had occurred in the past six months as a consequence of the underlying disease. Seasonal consumption of specific food items was also taken under consideration. The third part of the questionnaire included questions about food groups or specific food items that probably created troubles to the patients before the disease onset, the dietary habits changes after diagnosis, the fear of anointment of specific food items, etc.

Data collection

Data were obtained by standardized interviews lasting approximately one hour, conducted by the first of the authors. Healthy controls (except 8 of them, who were interviewed as well) completed the questionnaires after receiving them by e-mail. This group did not complete the third part of the questionnaire.

Statistical analysis

Contingency tables and chi-square tests were employed for the statistical analysis of nominal variables, and non-parametric tests (Mann-Whitney test) for the analysis of interval variables. The strength of the association between the intake of food groups and the risk of CD was verified with logistic regression analysis.

RESULTS

Foods with statistically significant difference between controls and newly diagnosed patients are shown in table I. As it can be seen in the table, statistically significantly decreased consumption of milk and yogurt, fruits, citrus, vegetables, carrots, legumes, fish and selfish, honey and nuts was noticed in the group of "new" patients with CD as compared with the group of healthy controls. Thus, patients with a recently established diagnosis of CD (group of "new" patients) described significantly less consumption of fruits *(P=0.0001)*, citrus *(P=0.0001)*, vegetables *(P=0.0001)*, carrots *(P=0.0001)*, fish and selfish *(P=0.001)*, honey (*P=0.003*), legumes *(P=0.036)*, nuts (*P=0.038*), and milk and yogurt *(P=0.042)*, in comparison with the group of healthy controls.

On the other hand, an increased consumption of fried food (P=0.0001), pasta (P=0.0001), alcohol drinks (P=0.009) sugar (P=0.02), olive oil (P=0.038), margarine (P=0.038) and fat (P=0.041), was obtained in the group of newly established diagnosis of CD ("new" patients with CD)

as compared with the group of healthy controls.

TABLE I
Foods with statistical significant differencesbetween "new" patients and healthy controls

Variable	*"New" patients*	*Healthy controls*	P value
Milk-yogurt	4.0	5.42	0.042
Fruit (total)	4.0	6.47	0.0001
Citrus fruit	1.93	4.09	0.0001
Vegetable (total)	5.36	6.68	0.0001
Carrots	1.21	3.11	0.0001
Rice	5.29	4.47	0.046
Pasta	6.5	4.74	0.0001
Legumes	2.29	3.05	0.036
Fish-shellfish	2.21	3.53	0.001
Fried food	4.00	2.21	0.0001
Sugar-sweeteners	6.00	4.16	0.002
Honey	1.36	2.95	0.003
Fats and oils	7.29	6.63	0.041
Olive oil	7.07	6.42	0.038
Margarine	3.71	2.05	0.0001
Nuts	1.21	2.21	0.005
Alcohol	5.3%	43%	0.009
Fast-food	5.3%	35.7%	0.004

Foods with statistical significant difference between "new" patients and "old patients" are shown in table 2. As the table indicates, statistically significantly decreased consumption of fish-shellfish food *(P=0.018),* and tea *(P=0.026)* and significantly increased consumption of fried food *(P=0.002),* margarine *(P=0.0001)* and coffee *(P=0.018)* was noticed among newly diagnosed patients in comparison with "old" patients (table II).

TABLE II
Foods with statistical significant differences between "new" patients and "old patients"

Variable	*"New" patients*	*"Old patients"*	P value
Fish-shellfish	2.21	3.40	0.018
Fried food	4.00	2.13	0.002
Honey	1.36	2.53	0.094
Margarine	3.71	1.60	0.0001
Coffee	64.3%	13.3%	0.018
Tea	7.1%	46.7%	0.026

TABLE III
Foods with statistical significant differencesbetween "old" patients and healthy controls

Variable	*"Old" patients*	*Healthy controls*	*P value*
Milk-yogurt	2.93	5.42	0.042
Fruit (total)	4.60	6.47	0.0001
Citrus fruit	2.67	4.9	0.001
Vegetable (total)	4.73	6.68	0.0001
Carrots	1.47	3.11	0.0001
Rice	5.53	4.47	0.022
Legumes	2.47	3.05	0.027
Sugar-sweeteners	5.47	4.16	0.002
Honey	2.53	2.95	0.003
Olive oil	7.20	6.42	0.038
Nuts	1.20	2.21	0.002
Alcohol	6.7%	43%	0.009
Refreshments	13.3%	57.9%	0.028

Table III shows foods with statistically significant differences between "old" patients in comparison with healthy controls. As the table indicates patients with a recently established diagnosis of CD (group of "new" patients) described significantly less consumption of citrus fruits *(P=0.001),* fruits (total) *(P=0.0001),* vegetables *(P= 0.0001),* carrots *(P=0.0001),* honey (*P= 0.003*), legumes *(P=0.027),* nuts (*P= 0.002*), alcohol *(P=0.009)* and refreshments *(P=0.028),* in comparison with the group of healthy controls. These differences were quite similar with those found between patients with newly established disease in comparison with healthy controls. On the contrary they consumed more rice *(P=0.022),* sugar-sweeteners *(P= 0.002),* and olive oil *(P=0.038).*

On logistic regression analysis foods remaining statistically significant were: margarine, pasta, fried foods, fat, olives, and sugar (foods that increase the risk of acquiring CD), and yogurt, honey, fruits, nuts, fish, and citrus fruits (foods that decrease the risk of acquiring CD) (table IV).

TABLE IV
Foods remaining statistically significant on logistic regression analysis (increased or decreased risk): "new" patients *vs.* healthy controls.

Variable	*Significance*	*Odds Ratio*	*95% CI - Lower*	*95% CI - Upper*
Alcohol	0.025	13.493	1.388	131.195
Margarine	0.007	6.305	1.643	42.187
Pasta	0.004	5.17	1.665	16.051
Fried	0.008	3.609	1.398	9.316
Fats-oil	0.038	3.539	1.071	11.699
Olive	0.047	2.596	1.014	6.644
Sug_sw	0.039	1.561	1.023	2.382
Rice (~)	0.117	1.555	0.896	2.698
Milk_yog	0.045	0.649	0.426	0.991
Pulses (~)	0.1	0.572	0.293	1.114
Honey	0.051	0.541	0.292	1.003
Fruits	0.013	0.297	0.114	0.774
Nuts	0.019	0.264	0.860	0.807
Fish Selfish	0.009	0.151	0.037	0.623
Vegetables	0.005	0.134	0.033	0.549
Carrot	0.003	0.037	0.040	0.333
Citrus fruits	0.002	0.031	0.152	0.652

Patients with CD that belonged to the group of "new" patients, were significantly overweighed (64%) as compared to the group of healthy people (26%) and patients with previously established CD (7%) *(P<0.046).*

DISCUSSION

Dietary factors have been implicated in the etiology of IBD from many years. Most of the studies investigated the influence of different kinds of foods in patients with IBD in comparison with normal people, while some other investigated the consumption of foods in newly established disease. However, it became quite evident that methodological considerations that usually arise when studying any pre-illness

diet, relate both to the mnemonic bias that occur when patients are asked about their past diet and the possibility that the disease and its symptoms have influenced their nutritional habits.

In this study, in order to counterbalance the above mentioned parameters, the patients were interviewed within 2-4 months from the time of diagnosis. Furthermore, they were questioned about food consumption during the last two years, but before any symptoms occurred. That is why they were also asked to describe any change in food consumption during the last six months, therefore increasing the reliability of the results. The statistical analysis methods used in this study (contingency tables and chi-square tests for the nominal and Mann-Whitney test for interval variables) were the appropriate ones according to the kind and nature of the goals of the study, the information collected and the sample size. That statistical analysis in fact pointed out the differences in food consumption between the groups. Logistic regression analysis was used to estimate the strength of each observation.

The results of our study showed that when compared controls and newly diagnosed patients an increased consumption of milk and yogurt (P=0.042), fruits (P=0.0001), citrus (P=0.0001), vegetables (P=0.0001), carrots (P=0.0001), legumes (P=0.036), fish and selfish (P=0.001), honey (P=0.003), and nuts (P=0.038), was associated with decreased risk for CD. On the other hand, significantly increased intake of fat (P=0.041), olive oil (P=0.038), margarine (P=0.038), sugar (P=0.02), alcohol drinks (P=0.009), fried food (P=0.0001), and pasta (P=0.0001), was noticed on recently diagnosed patients in comparison with the healthy control group. On logistic regression analysis foods remaining statistically significant were: margarine, pasta, fried foods, fat, olives, sugar (increased risk), and yogurt, honey, fruits, nuts, fish, and citrus fruits (decreased risk).

Food consumption and dietary choices usually reflect a life-style model. High consumption of refined and fast food, rich in saturated and total fat and different kinds of additives, accompanied by a low consumption of fruit, vegetables, legumes and other "healthy" food, is quite typical for most western-type societies. In this study, the differences between health controls and newly diagnosed patients were quite well established. Furthermore, the content of food in nutrients varies among different geographic regions around the world. Different kinds of cattle or farming techniques e.g. organic or conventional farming, food process and preparation could also affect their overall nutrient content. Local or seasonal food consumption and dietary patterns vary among different populations. All the above are crucial parameters when trying to conduct any conclusion about the protective or aggravating role of food or nutrients relatively to any disease and might also explain probable disparities among studies. In this study national and seasonal consumption was taken under consideration.

Dietary risk factors previously suggested to be related (at least epidemiologically) with CD include sugar and refined carbohydrates. Comparisons between patients with CD and normal people revealed increased consumption of refined sugar among the patients either before or after diagnosis of bowel disease (16-21).

The possibility that this was the result of patients' food choices, because of the disease's symptoms, has always been a

subject of debate. In this study, however, the pattern of increased sugar consumption was recorded among newly diagnosed patients, before the symptoms occurred. An explanation could be related to the increased intestinal permeability (22) and altered immune response (23).

In recent years, special attention has been paid to the lipid components of the diet as triggers of CD (15). Increased daily intake of n-6 polyunsaturated fatty acids relatively to n-3 PUFAs, which is considered to increase the proinflammatory leukotrienes B4 and alter arachidonic metabolism was related to the increased incidence of CD in Japan5. In our study, newly diagnosed patients also used to consume more total fat and oils and olive oil than healthy controls. Olive oil is globally known for its antioxidative properties and a potential aggravating involvement in such an inflammation process might be rather worth mentioned. However, the increased fried food consumption and the decreased vegetable one (vegetables are suggested to increase olive's oil antioxidative capacity) that were also emerged in this study, as well as the n-6/n-3 ratio mechanism previously proposed, could give a possible explanation for this observation. We have also noticed a high margarine and fast-food consumption (a diet rich in total and saturated fat) in newly diagnosed patients with CD. On the contrary, fish and shellfish consumption seemed to have a protective role against CD, in part maybe because of their high content in n-3 PUFA, which are well documented for their ability to control inflammation and enhance immunity (24). However, the content in n-3 PUFA, as well as n-6 and other nutrients, usually varies among different kinds of fish and shellfish and probable among different regions around the world. This fact could explain the discrepancy observed in the study of Sakamoto et al. (15) who found a positive association between fish and shellfish consumption and development of CD. In Greece, consumption of rich in n-3 PUFA fish (such as sardines) is part of local or seasonal nutrition patterns. It is worth mentioning that a pattern of foods characterized by fish, grains, and nut consumption was inversely associated with CD in children of both genders indicating that this specific dietary pattern could be associated with lower risks for CD in children (25).

Some previous studies have identified low intake of fruit and vegetables among CD patients indicating that the consumption of citrus fruit, fruit juices and vegetables could lower the risk of the development of IBD (9, 14, 26). However, most of the studies have not investigated long-standing disease; therefore the described results could be attributed to the disease itself. In our study, increased consumption of fruit (especially citrus fruits) and vegetables (especially carrots) was lower among CD patients, indicating their possible protective role. Fruits and vegetable are rich in a variety of phytochemicals that are related to inflammation control. The consumption of vegetables and fruits was also inversely associated with CD development in children in both genders (25).

As far as fiber consumption is concerned, a previous study showed an inverse relationship between consumption of bran and onset of CD (27). However, it is difficult to determine whether the potentially protective effect of fiber is due to its action itself or to other micronutrients contained in fruit and vegetables. The utility of low

refined carbohydrate diets in the treatment of CD has previously been suggested (28), although extensive clinical trials have not confirmed the benefits of this diet (29). It is possible –at least theoretically- that short-chain fatty acids are particularly worthy of note and are generated during the colonic fermentation of dietary fiber. A quantitative short-chain fatty acids deficiency or their oxidation by colonocytes have been implicated in the physiopathology of ulcerative colitis (30) and short-chain fatty acids *in vivo* oxidation is also lower in affected patients (31).

In our study, alcohol consumption was found to be higher among newly diagnosed CD patients suggesting that it might act as a risk factor. This finding has not been previously described. However, some suggest a possible mechanism through alteration in hepatic metabolism that results in functional iron deficiency causing impaired immune function (32). Other vitamins such as riboflavin and folate deficiency may also alter immune functions and impaired control of chronic inflammation (33). Even though this study was not designed to estimate nutrient but food consumption, its results underline that there are considerable differences among newly diagnosed CD patients' and healthy controls' diet that should be further investigated.

Finally, one interesting finding of our study was related to the presence of obesity in newly diagnosed patients compared to "old" patients and normal controls. Newly diagnosed patients were significantly overweighed (64%) compared to healthy people (26%) and old patients (7%). Obesity in patients with CD has previously been considered unusual. In a recent study from Scotland the authors described a percentage of 18% of the IBD population to be obese in comparison to approximately 23% of the Scottish population on a whole (34). A further 38% of patients were over-weight, the same percentage as the general population. Finally, there were significantly more obese men and women with CD than with ulcerative colitis (34). Although obesity in Greece has increased considerably over the last years, it seems that this finding is not the result of a chance and must be further investigated.

CONCLUSIONS

Significant differences in many food items between newly diagnosed Greek patients with CD and normal people certainly exist. Our results suggest that specific dietary patterns could be associated with higher or lower risks for CD in adults. Whether these dietary factors are important for the development of CD or modulate the effect of other environmental factors is unknown. Again is unknown if dietary modulations applied before or after the establishment of diagnosis of CD could delay the appearance of CD or benefit the course of CD. Personalized diets may be especially important for patients with CD by excluding a number of food items35. The available data suggest that the changes in the composition and characteristics of the diet which typifies modern life have been accompanied by substantial changes in the epidemiology of IBD in developed counties. Taking into consideration the results of the present study we suggest that larger studies aiming to investigate the influence of diet on the pathogenesis or the activity of the disease on subjects with different genetic background could produce important results.

EFFECTS OF SARCOPENIA AND SARPOPENIC OBESITY ON THE HEALTH STATUS OF EARLY POPULATION (Abstract). Sarcopenic obesity (SO) is a category of obesity that occurs predominantly in elderly people who experience an increase in adipose tissue associated with muscle mass loss. It is associated with higher mortality rates than sarcopenia and obesity alone, thus confirming the need to redefine obesity and sarcopenia based on the new parameters-the simple determination of the body mass index becoming unsatisfactory. Quantification of obesity is done by measuring through various imaging techniques the percentage of fat mass, muscle mass/lean body tissue and bone mass or the ratio of visceral fat to thigh muscle area (determined by computed tomography). Redefinition of sarcopenia is a decrease in striated muscle mass associated with either a decrease in muscle strength (hand grip strength) or reduced physical activity ("gait speed"); when all three criteria are met, we talk of severe sarcopenia. These new parameters result from the fact that in sarcopenia there is no parallel loss of muscle mass and muscle strength, and that the alteration of muscle strength is a more important risk factor for overall mortality than the decline in muscle mass. For these reasons, quantification of the degree of sarcopenia is done by individual assessment of the three parameters: muscle mass, muscle strength and physical activity. Although currently there is no consensus on the definition of SO, all authors agree on its serious consequences on the quality of life of the elderly, favoring cardiovascular and metabolic diseases, aggravating frailty, significantly increasing the risk of falling and of developing disabilities, and finally, increase in overall mortality. Today, SO identification, prevention and treatment become priority interventions in the therapeutic plan of the elderly to ensure successful aging and maintain a quality of life corresponding to expectations. **Keywords**: VISCERAL OBESITY, SARCOPENIA, SARCOPENIC OBESITY, ELDERLY.

Sarcopenia is the loss of muscle mass and strength that occurs with aging. There is a progressive decrease in muscle mass of approximately 8% per decade between 40 and 70 years, and doubles after the age of 80 years. This condition affects 30% of patients over the age of 60 and about 50% of those over 80 years (1). Along with sarcopenia, there is an increase in visceral fat, overweight and obesity being particularly common in this population segment. The association of these two entities has

led to the emergence of a new concept termed sarcopenic obesity.

Sarcopenic obesity (SO) was first defined by Baumgartner (2) in 2010 as the association between sarcopenia and obesity (as measured by Dual-energy X-ray absorptiometry). SO is considered a category of obesity that occurs predominantly in elderly patients who experience an increase in adipose tissue associated with muscle mass loss. (3). Studies show that SO is associated with higher mortality risk than sarcopenia and obesity alone. In fact, there is no unanimously accepted definition of SO because there are no unanimously accepted definitions for obesity and sarcopenia.

Defining obesity

Obesity is a major public health problem and a major risk factor for morbimortality through cardiovascular and metabolic diseases. The prevalence of obesity in the adult and elderly population has doubled since 1980 and is steadily increasing (3,4). The World Health Organization defines obesity - regardless of age - as associated with BMI values> 30 kg/m2 and WC > 102 cm for men and > 88 cm for women (central obesity). Studies conducted over the past 10 years showed that this definition should be supplemented with other parameters provided by body composition measurement techniques, most commonly used being Dual-energy X-ray absorptiometry (DXA) and bio impedance (BIA). These parameters newly included in the definition of obesity are the percentage of fat mass, muscle mass /lean body tissue and bone mass, or the ratio of visceral fat to thigh muscle area (determined by computed tomography) (5, 6).

This reassessment of the definition of obesity was necessary due to the conflicting data known as the obesity paradox. These data show that in the elderly population overweight and obesity (measured by Body Mass Index) are associated with a decrease in all-cause mortality, particularly in cardiovascular mortality. This contradicts the unanimously accepted data that obesity is a major cardiovascular risk factor with a devastating impact on mortality in the adult population. The explanation for this paradox seems to be that aging is associated, among others, with an increase in visceral fat but also with a progressive loss of muscle mass (sarcopenia). Sarcopenia is significantly associated with the preexisting cardiovascular risk factors; in addition, it is associated with important metabolic disorders, physical disability and increased mortality. The coexistence of sarcopenia with obesity in the elderly determines, on one hand, the prolongation of life through the beneficial effects of obesity and, on the other hand, severe impairment of the quality of life through the negative effects of sarcopenia (3, 6, 7, 8).

Obesity paradox is explained by the presence of SO, and to demonstrate this phenomenon it became necessary to quantify both sarcopenia and obesity; in this context, the simple definition of obesity by body mass index is unsatisfactory (7, 8).

Defining sarcopenia

The term sarcopenia was first proposed in 1989 by Irwin Rosenberg (from Greek "sarx" = meat, "penia" = loss) to describe the decrease in the muscle mass characteristic to the aging process (9).

Sarcopenia, part of the frailty syndrome in the elderly, had neither a unanimously accepted definition nor consensus diagnosis, codes or treatment guidelines. To address these shortcomings, the European Union Geriatric Medicine Society (EUGMS) decided in 2009 to create a sarcopenia working

group that would develop operational definitions and diagnostic criteria for sarcopenia to be used in clinical practice as well as in research studies (10). Other European scientific organizations (European Society of Clinical Nutrition and Metabolism (ESPEN), International Nutrition and Aging Academy (IANA) and the International Association of Gerontology and Geriatrics - Europe Region (IAGG-ER) were invited to join this group. The unanimously accepted conclusions have led to a new definition of sarcopenia, considered to be the decrease in the striated muscle mass associated with either the decrease in muscle strength (grip strength) or with reduced physical activity ("gait speed"); when all three criteria are met, we talk of severe sarcopenia (European Working Group on Sarcopenia in Older People).

Pathophysiological, sarcopenia is an inflammatory state triggered by pro-inflammatory cytokines and oxidative stress and resulting in age-related muscle mass loss (11,12) (fig 1).

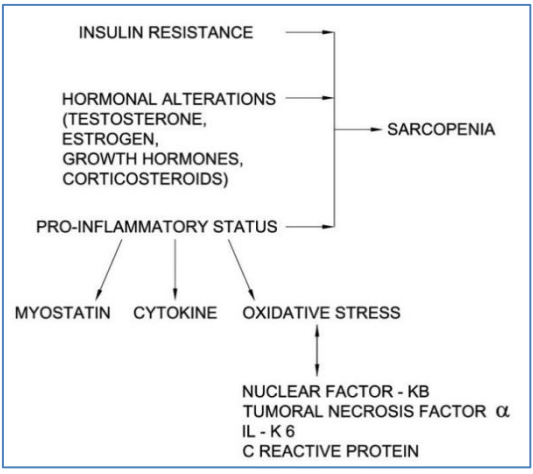

Fig. 1. Factors determining the occurrence and persistence of sarcopenia in the elderly

Sarcopenia is directly associated with insulin resistance, metabolic syndrome, and type 2 diabetes mellitus. Concurrently, insulin resistance favors muscle fiber atrophy and mitochondrial dysfunction, aggravating sarcopenia. Of the pro-inflammatory factors, a special mention is given to myostatin (growth/differentiation factor 8) that inhibits muscle cell growth and differentiation and seems to be not only a key mediator in sarcopenia but also a promising therapy (4, 13, 14).

There is a great deal of evidence that in sarcopenia there is no parallel loss of muscle mass and muscle strength (15). This finding has a special significance because the alteration in muscle strength is a more important risk factor of all-cause mortality than the decline in muscle mass (16). For these reasons, the degree of sarcopenia is quantified by individual assessment of the three parameters: muscle mass, muscle strength and physical activity.

Muscle mass is measured by several imaging techniques: computed tomography (CT), magnetic resonance imaging (MRI), dual energy X-ray absorption (DXA), bio impedance, and anthropometric measure-

ments.

Muscle strength is most often assessed by determining the hand grip strength (although for the assessment of physical function the changes occurring in the lower limbs are more relevant than those in the upper limbs), because it is a simple technique and the obtained results have a high degree of reliability (8).

Physical activity is often assessed with Short Physical Performance Battery (SPPB) based on gait speed, chair stand and balance tests, timed up and go test, 400-meter walk test, six-minute walk test (8.17).

Defining sarcopenic obesity

SO is considered as a stand-alone entity due to the accumulation of data suggesting that sarcopenia and obesity share common etiopathogenic elements and mutually potentiate one another negatively, leading to an increased risk of all-cause and particularly of cardiovascular morbimortality, increases more than the risks of obesity and sarcopenia taken separately (11, 18) (fig 2).

Increase in visceral fat is associated with an increase in inflammation markers, particularly of oxidative stress and pro-inflammatory cytokines; they will lead to worsening of sarcopenia with decrease in physical activity and energy expenditure, elements that will favor visceral fat increase, closing the circle through which obesity and sarcopenia potentiate each other negatively (19).

Obesity and sarcopenia share several common elements which cause the onset of SO (fig 3).

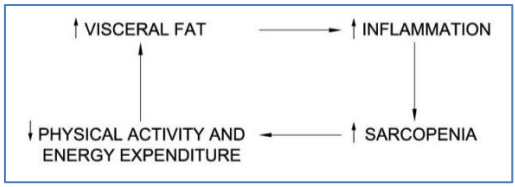

Fig. 2. Mutual negative potentiation of sarcopenia and obesity in SO.

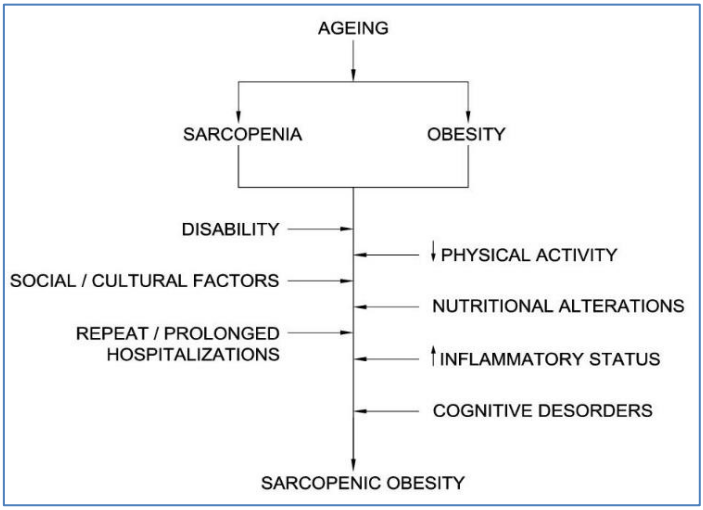

Fig. 3. Factors favoring the occurrence of Sarcopenic Obesity

Thus, sarcopenia per se is a characteristic of aging, responsible for decreased physical activity and increased inflammatory status; at the same time there is an increase in aging-related increase in adipose tissue associated with inadequate nutritional intake (low protein intake), which will further alter the balance between fat mass and muscle mass, favoring SO. Associated to these pathogenic links are a number of social/cultural factors that alter the lifestyle of the elderly, eventual disabilities caused by concomitant chronic illnesses that may be associated with repeat hospitalizations and possible cognitive disturbances, with disastrous results for lean mass - fat mass balance.

Although there is no consensus on the definition of SO, all authors agree on its serious consequences on the quality of life of the elderly, by favoring the occurrence of cardiovascular and metabolic diseases, aggravating frailty, significantly increasing the risk of falls and disabilities, finally causing an increase in all-cause mortality (19, 20, 21, 22) (fig 4).

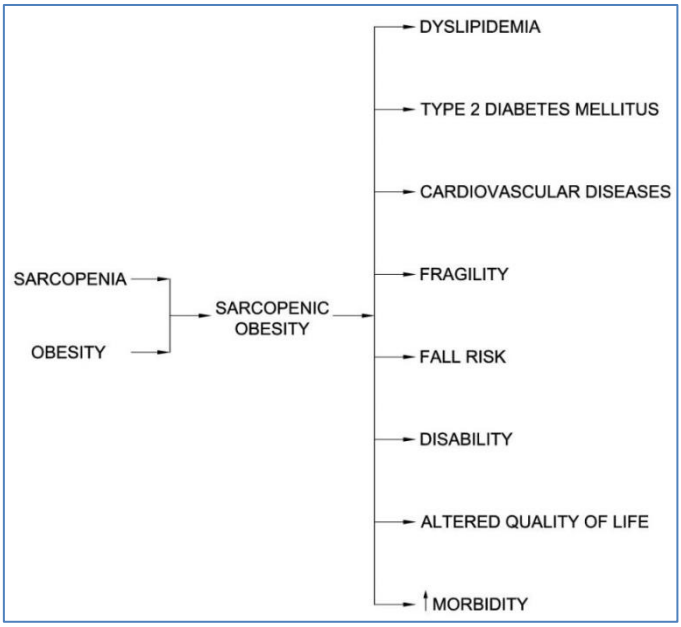

Fig. 4. Consequences of sarcopenic obesity on the state of health of the elderly population

For these reasons, prevention/improvement of SO becomes a very important task. Studies conducted in this field agree that a complex action is required both for the improvement of sarcopenia and fatty mass reduction. Maintaining/improving muscle mass and strength and maintaining adequate weight through physical activity and adequate nutrition is essential for preserving independence in old age - assessed with the help of activities of daily living (ADL) and instrumental activities of daily living (IADL) scales, especially in the elderly patient with cardiovascular and metabolic diseases (23, 24, 25). Adequate protein intake, optimally achieved by taking nutritional supplements based on essential amino acid mixtures, will result in a decrease

in insulin resistance and improvement of the degree of sarcopenia. Severe diets are not recommended, as they will not only lead to fat mass loss, but also to the "melting" of the muscle mass, with the occurrence of cachexia (26, 27, 28).

CONCLUSIONS

SO is considered as a stand-alone entity due to the accumulation of data suggesting that sarcopenia and obesity share common etiopathogenic elements and potentiate one another negatively, leading to an increase in the risk of all-cause and especially cardiovascular morbimortality higher than the risks of obesity and sarcopenia taken separately. These common elements of obesity and sarcopenia initiate a vicious circle in which the two entities potentiate one another negatively. Although there is no consensus on the definition of SO, all authors agree on its serious consequences on the quality of life of the elderly, favoring cardiovascular and metabolic diseases, aggravating frailty, significantly increasing the risk of falls and disabilities, finally causing an increase in all-cause mortality. For these reasons, prevention/improvement of SO became a very important task. Choosing the type and degree of personalized exercise should be associated with a correct protein intake, optimally achieved by the administration of nutritional supplements based on essential amino acid mixtures that will result in decreased insulin resistance and improved degree of sarcopenia degree. Selection of the therapeutic plan should be supervised by qualified personnel to avoid the severe diets that not only lower the fat mass, but also "melt" the muscle mass, leading to cachexia.

ESSENTIAL HYPERTENSION IN CHILDREN – RISC FACTORS AND TARGET ORGAN DAMAGE (Abstract): Regarding that systemic hypertension is an important condition in childhood, we try to clarify existing data about this pathology. **Material and methods**: The aim of our study was to evaluate the incident cases of essential hypertension in children admitted during a four years period in the Children Hospital "Sf. Maria" Iaşi, Romania. The study included 60 children with essential hypertension. **Results**: 10 (16,7%) of children were in prehypertension group, 38 (63,3%) have stage 1 hypertension and 12 (20%) have stage 2 hypertension. We objectivate a different gender distribution -boy/girl: 1,5/1. The frequency of essential hypertension increased with age, the incidence was higher over 14 years. We established a statistically significant relationship between the essential hypertension body mass index and prematurity (gestation age under 37 weeks). Left ventricular hypertrophy was objectivated in 26,7% of cases. **Conclusions**: Essential hypertension in children is a pathology with increasing prevalence nowadays. This is due to synergic action of multiple risk factors involved. That is why is important to know and to prevent as much as possible this disease.
Key words: ESSENTIAL HYPERTENSION, BLOOD PRESSURE, LEFT VENTRICULAR MASS INDEX.

Hipertensiunea arterială (HTA) reprezintă cauza majoră a bolilor cardiovasculare (1). S-a demonstrat că HTA este principala cauză de mortalitate în lume şi a doua cauză de morbiditate (după prematuritate) la copil (1). Prevalența şi rata de diagnostic a HTA la copil par să fie în creştere, în principal datorită obezității infantile (3, 4). Studiul nostru urmăreşte să aducă unele clarificări privind datele demografice, factorii de risc şi afectarea organelor țintă în cazul prezenței HTA esențiale (HTAE) la copiii din Moldova, pe o perioadă de 4 ani.

MATERIAL ŞI METODE

Au fost incluse în studiu cazurile de HTAE internate, în perioada 2007 - 2010 în Spitalul de Urgențe pentru Copii „Sfânta Maria" Iaşi, provenite din județele Moldovei. Lotul de studiu a fost selectat după

măsurarea tensiunii arteriale (TA) prin metoda ascultatorie, adaptată dimensiunilor antropometrice ale copilului, pe baza înregistrării în dinamică a trei valori presionale, în trei momente diferite, care să depăşească percentilul (p) 95 pentru talie, vârstă şi sex, utilizând nomogramele propuse de ultimul ghid în domeniu (5).

Diagnosticul a fost stabilit pe criteriile specifice respectivei entități patologice, identificate prin anamneză, examen fizic şi explorări paraclinice, fiind astfel identificați 60 de copii cu HTAE. Copiii cu indicele masei corporale (IMC) mai mic decât p 85, pentru vârstă şi sex, au fost considerați normoponderali; cei cu IMC între p85 şi p95, supraponderali, iar în cazul celor cu IMC mai mare decât p95, au fost incluşi în grupul obezilor.

Evaluarea ecocardiografică a fost efectuată de acelaşi investigator folosind un ecocardiograf „Vivid 3 pro" cu un transductor de 3,5 MHz. Ecografia şi procesarea datelor s-a realizat în concordanță cu ghidurile Societății Americane de Ecocardiografie, înregistrând valorile medii din trei cicluri cardiace consecutive (6). În modul M s-au efectuat măsurătorile septului interventricular (SIV) în diastolă, a diametrului diastolic al ventriculului stâng (DdVs) şi peretelui posterior al ventriculului stâng (PpVs) în timpul diastolei. Aprecierea încadrării în intervale fiziologice sau patologice de variație a acestor parametri s-a realizat prin compararea cu valorile medii inserate în literatura de specialitate (7). Modificarea anatomică principală urmărită a fost hipertrofia ventriculară stângă (HVS), evaluată prin calcularea masei ventriculului stâng (MVS) cu ajutorul formulei lui Devereux (8). Masa calculată a ventriculului stâng a fost ulterior raportată la talia ridicată la puterea 2,7 exprimată în metri pentru a minimiza efectele vârstei, sexului şi statusului ponderal (9, 10). Astfel am obținut indicele masei ventriculului stâng (IMVS). Nu există încă un consens cu privire la valorile de referință ale IMVS. Pentru definirea HVS am luat în considerare fie o valoarea a IVMS mai mare sau egală cu p 95 pentru sex (corespunde valorilor de 36,88g/$m^{2,7}$ la fete şi 39,36 g/$m^{2,7}$ la băieți), fie o valoare mai mare sau egală cu 51 g/$m^{2,7}$ (valoare peste p 99, care se asociază cu un risc de morbiditate cardiovasculară de 4,1 ori mai mare la adulții hipertensivi) (11).

Pentru evaluarea statistică a datelor s-a utilizat programul de analiză *SPSS 17.0* (SPSS Inc., Chicago, Illinois). Semnificația statistică de prag a fost aleasă la valoarea p = 5% şi corespunzător intervalul de încredere a fost de 95%.

REZULTATE

În studiu au fost incluşi 60 de copii cu HTAE, debutul HTA la fiecare copil a fost, convențional, considerat a fi momentul diagnosticului (abordarea inițială), deoarece în practică este imposibil a depista debutul real al HTAE la copil. În studiul nostru, distribuția pe sex masculin/feminin a fost de 1,5/1. Vârsta medie a pacienților de sex feminin fost de 13,96 ± 2,36 ani, iar pentru sexul masculin a fost de 13,17 ± 2,62 ani. Evaluarea pe grupuri de vârstă şi sex a dovedit că frecvența cea mai mare de apariție a bolii a fost întâlnită la grupul de vârstă de peste 14 ani. De asemenea, s-a constatat o frecvență de 2,15 ori mai mare a HTAE la copiii din mediul urban. S-a obiectivat o diferență semnificativă statistic între statusul ponderal evaluat prin intermediul IMC la cele două sexe în favoarea băieților (p=0,016) (tab. I).

TABELUL I

Parametri analizaţi în hipertensiunea arterială esenţială la copil

Parametru	Categorii	Stadiul HTA (număr pacienţi)			total	p
		prehiper tensiune	HTA stadiul 1	HTA stadiul 2		
Vârsta (ani)	7-10	3	1	4	8	
	10-14	4	10	5	19	
	> 14	3	27	3	33	
Sex	masculin	10	15	11	36	p=0,004
	feminin	0	23	1	24	
Mediul de proveniență	urban	10	23	8	41	p = 0,310
	rural	0	15	4	19	
Indice de masă corporală (percentil)	< p85	8	25	3	36	p=0,0002
	p85 - p95	1	11	2	14	
	> p95	1	2	7	10	
Vârsta gestaţională (săptămâni)	<37	0	2	6	8	p<0,001
	37 - 42	9	33	5	47	
	>42	1	3	1	5	
Indicele de masă al ventriculului stâng (percentil)	< p95	8	28	8	44	p=0,001
	≥p95 <p99	1	5	1	7	
	>p99	1	5	3	9	

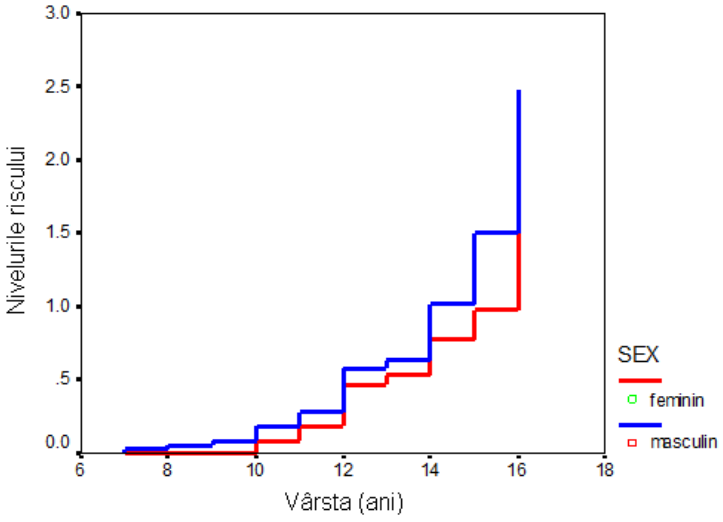

Fig. 1. Distribuţia pe sex a riscului apariţiei HTAE

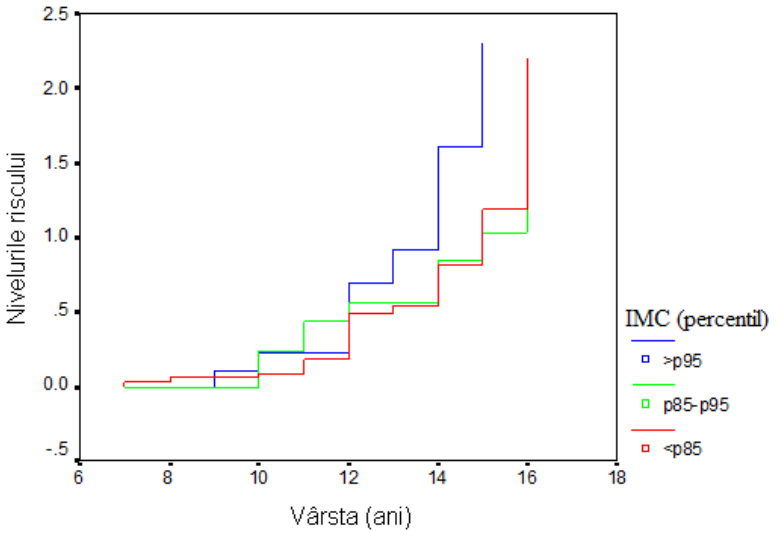

Fig. 2. Riscul apariției HTAE în relație cu valorile IMC

În relație cu stadiul HTA s-a remarcat frecvența crescută la copiii supraponderali mai frecvent asociată cu HTA stadiul 1, în timp ce la obezi s-a asociat cu HTA stadiul 2 (χ^2=17,51; GL=2; p=0,0002). Copiii cu IMC peste p 95, începând cu vârsta de 12 ani, prezintă cel mai mare risc de apariție a HTAE (fig. 2).

Analiza statistică a evidențiat faptul că vârsta gestațională sub 37 de săptămâni induce un risc crescut de apariție a HTA începând cu vârsta de 12 ani.

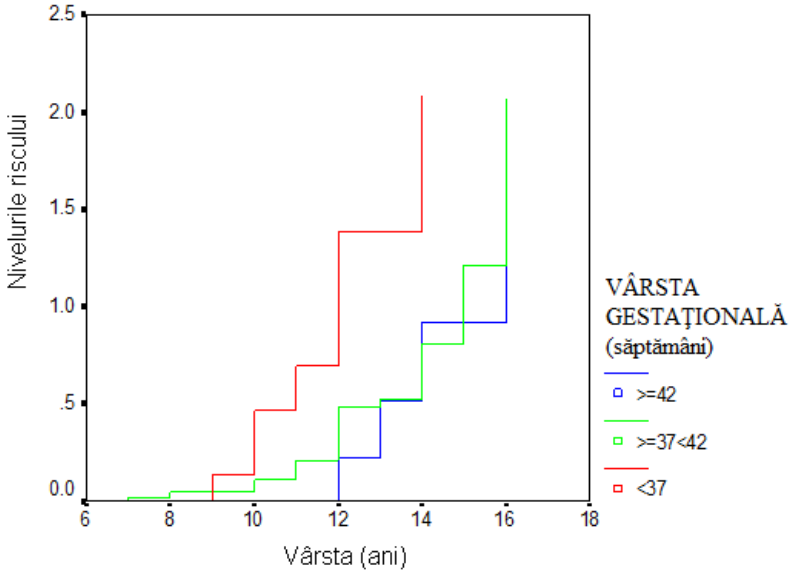

Fig. 3. Riscul apariției HTAE în relație cu vârsta gestațională

DISCUŢII

În relaţie cu stadiul HTAE lotul de studiu a fost împărţit în 3 grupuri. Astfel 10 (16,7%) copii s-au încadrat în grupul cu prehipertensiune, 38 dintre copii (63,3%) au fost incluşi în HTA stadiul 1 şi doar 12 dintre copii (20%) au aparţinut în grupul cu HTA stadiul 2. În studiul nostru s-a remarcat o creştere a frecvenţei HTA cu vârsta, cu o incidenţă mai mare la sexul masculin. Datele din literatură arată că nivelurile TA cresc odată cu vârsta la ambele sexe, iar diferenţele între acestea sunt remarcate precoce. La fete tensiunea arterială sistolică (TAS) creşte mai rapid între 6-11 ani comparativ cu perioada 12-17 ani. La băieţi se remarcă opusul acestui fenomen: o creştere mai rapidă se observă între 12-17 ani comparativ cu perioada 6-11 ani. Între 12-14 ani băieţii tind să aibă niveluri tensionale mai mari decât fetele (12). De asemenea, studiul de faţă a obiectivat o frecvenţă de 2,15 ori mai mare a HTAE la copiii din mediul urban. Acest fapt ar putea fi pus pe seama obiceiurilor alimentare nesanogene prezente frecvent în mediul urban, deşi diferenţa nu este semnificativă statistic. S-a remarcat asocierea dintre supraponderabilitate şi HTAE stadiul 1 şi dintre obezitate şi HTAE stadiul 2 ($\chi 2=17,51$; GL=2; p=0,0002). Copiii obezi prezintă cel mai mare risc de apariţie a HTA începând cu vârsta de 12 ani (fig. 2). Dacă la o determinare a prevalenţei HTAE la copil, după recomandările Task Force, aceasta era de aproximativ 1% (13), într-un studiu epidemiologie mai recent, realizat pe 5100 cazuri, prevalenta generală a HTA (după trei măsurători), a fost de 4,5% (14). Aceasta a fost explicată prin asocierea cu valorilor crescute ale IMC.

În ceea ce priveşte prematuritatea s-a remarcat un risc mai mare de apariţie a HTAE după vârsta de 12 ani, la copiii cu vârsta gestaţională mai mică de 37 de săptămâni (fig. 3). Studiile lui Barker (15) arată că asocierea independentă dintre greutatea mică la naştere şi riscul de hipertensiune şi boli cardiovasculare a fost evidenţiată la multiple populaţii din diverse zone geografice (16, 17, 18). În general copiii născuţi prematur prezintă un risc crescut de a dezvolta HTAE. Un studiu publicat în anul 2010 (19) a evidenţiat o TAS în medie cu 10 mmHg mai mare la adolescenţii şi adulţii tineri născuţi prematur comparativ cu cei născuţi la termen.

Pentru evaluarea afectării organelor ţintă secundar hipertensiunii a fost cuantificată hipertrofia ventriculară stângă prin intermediul IVMS.

26,7% dintre copiii din lotul de studiu au avut HVS, iar 15% dintre aceştia au fost diagnosticaţi cu HVS pe baza IMVS mai mare decât p 99, care se asociază cu un risc de morbiditate cardiovasculară de 4,1 ori mai mare la adulţii hipertensivi (9). Analizând valorile individuale ale IMVS, înregistrate la lotul de studiu, s-a constatat că statistic nu s-au evidenţiat diferenţe semnificative între sexe, medii de provenienţă şi grupuri de vârstă ale valorilor IMVS în contrast cu datele din literatură. Treiber et al (20) au investigat asocierea dintre IMVS şi TA la 84 de copii, cu istoric familial de HTA, demonstrând corelaţii semnificative între IMVS şi greutate, sex (mai mare la băieţi), vârsta, TAS de repaus.

CONCLUZII

În ultimii ani HTAE la copil a înregistrat o prevalenţă în creştere, urmare a acţiunii sinergice a multiplilor factori de risc implicaţi. Studiul nostru a remarcat un impact important al prematurităţii şi obezităţii asupra dezvoltării HTAE la copil. De asemenea, s-a evidenţiat o creştere a frecvenţei HTAE odată cu vârsta, atât la sexul masculin, cât şi

la feminin. Impactul HTA asupra organelor țintă, obiectivat prin IMVS, nu a fost dependent de vârstă, sex sau mediul de proveniență al copiilor incluşi în studiu.

CONTRIBUTIONS TO THE IMPLEMENTATION OF SCREENING TESTS FOR ASSESSING THE NEUROPSYCHIC DEVELOPMENT IN CHILDREN (Abstract): Currently, in Romania the general practitioner does not use screening tests to detect the developmental problems in children. That might be the reason why many cases are diagnosed too late. **Aim**: To evaluate the impact and the usefulness of a screening tool for neurodevelopmental disorders in primary care. **Material and methods**: This trans-sequential study was carried out a on a series of 324 children under the age of 5 in the interval January 2007–December 2010. The neurodevelopmental status of the children was assessed by two methods: routine clinical assessment, and ASQ screening tools. **Results**: Compared to routine assessment, by which 33 children (10,2%) with development delays have been detected, the use of parent-addressed questionnaires raised the detection percentage to 12% (6 more children). The use of parent-addressed questionnaires also improved the doctor-patient communication, increased the degree of parental involvement in their child's development stimulation, especially with regard to the malfunctions in verbal and cognitive behavior. **Conclusions**: The use of validated screening tests is a goal for improving the primary care practice. **Key words**: NEUROPSYCHIC DEVELOPMENT, SCREENING TEST, CHILD.

Medicul de familie, aflat în prima linie a sistemului medical, monitorizează dezvoltarea copilului prin evaluări periodice la diferite etape de vârstă. El este cel mai aproape de problemele familiei, poate sesiza şi corecta la timp carenţele nutriţionale şi de îngrijire, apreciază calitatea mediului familial, modul în care părinţii interacţionează cu copiii, condiţii care sunt esenţiale pentru dezvoltarea armonioasă, atât fizică, cât şi neuropsihică a acestora. În practica curentă, se efectuează o evaluare uzuală, nestandardizată a achiziţiilor psihomotorii ale copilului; depistarea întârzierilor în dezvoltare ţine atât de competenţa şi experienţa examinatorului, cât mai ales de timpul acordat consultaţiilor preventive. A depista cât mai precoce o tulburare în dezvoltarea neuropsihică a unui copil este de o importanţă majoră, deoarece aceasta este reversibilă până la un anumit nivel, recuperarea fiind posibilă doar dacă se corectează factorii stresanţi implicaţi. De aceea momentul intervenţiei este foarte important,

fiind condiţionat de precocitatea diagnosticului.

Studii de prevalenţă efectuate în Marea Britanie la nivelul anului 2005 de către Rydz et al. (1) arată o frecvenţă totală a dizabilităţilor în dezvoltarea copilului în primii 18 ani de viaţă, ce variază între 11,8 – 16,8%, cu impact negativ major asupra individului, a familiei şi a societăţii în ansamblu. Aceeaşi autori afirmă că, deşi există programe naţionale de supraveghere a dezvoltării neuropsihice a copilului, mai puţin de jumătate dintre pediatri utilizează testele screening, motiv pentru care doar 45 - 55% dintre copiii cu dizabilităţi (retard mental, disfuncţii ale limbajului etc.) sunt depistaţi până la vârsta şcolară, iar gradul de evidenţiere al tulburărilor de dezvoltare la copil, doar pe baza judecăţii clinice uzuale, nu depăşeşte 30%.

În Statele Unite, aproximativ 1 din 8 copii (12,5%) au dizabilităţi în dezvoltarea neuropsihică, tulburările din spectrul autist fiind diagnosticate la 1 copil din 110 (0,9%), cu o medie de 4 ani ½ a vârstei copilului în momentul diagnosticului (2).

În România, autismul - tulburare severă de dezvoltare de natură neurobiologică, rămâne o mare necunoscută. Cele mai multe dintre cazuri sunt diagnosticate târziu, după vârsta de 3 ani, deoarece nu există un sistem naţional de depistare timpurie, bazat pe verificarea indicatorilor de dezvoltare normală (motorie, cognitivă, emoţională), care să permită o orientare rapidă a medicului de familie spre o posibilă disfuncţie neuropsihică a copilului (www.autism.ro). În iulie 2010, Parlamentul României a adoptat legea autismului care prevede depistarea precoce a tulburărilor pervazive de dezvoltare prin aplicarea la nivelul practicii primare a unor chestionare tip screening, adresate tuturor copiilor cu vârste cuprinse între 1 şi 3 ani.

Studiul urmăreşte elaborarea unei metodologii pentru aprecierea dezvoltării neuropsihice a copilului la nivelul medicinii primare, care să permită intervenţia precoce şi creşterea interesului părinţilor pentru acest domeniu al dezvoltării copilului lor.

MATERIAL ŞI METODĂ

Studiul a fost efectuat în perioada ianuarie 2007 – decembrie 2010, utilizând un design mixt (studiu trans-secvenţial), pe un lot de 324 copii sub vârsta de 5 ani care au fost supravegheaţi longitudinal cu evaluare la diferite etape de vârstă. Subiecţii au fost selectaţi dintr-un grup de 425 de copii din Iaşi, născuţi în perioada octombrie 2004 – septembrie 2009, aflaţi în evidenţa cabinetului de medicină de familie, după următoarele criterii de excludere: copii cu malformaţii congenitale invalidante, cu encefalopatie hipoxic ischemică la naştere, hipotiroidism congenital, prematuri sub vârsta gestaţională de 35 săptămâni. Pentru toţi cei incluşi în lotul de studiu am solicitat şi am obţinut de la părinţi acordul de participare şi de folosire a datelor medicale, cu asigurarea confidenţialităţii şi protecţiei identităţii subiecţilor.

Consultaţia prevenţională de rutină a constat în: efectuarea unui examen clinic general, măsurători antropometrice, consemnate pe nomograme în percentile, aprecierea nestandardizată (după reperele cunoscute) a dezvoltării neuropsihice, consiliere preventivă şi nutriţională, imunizări.

La etapele de vârstă: 15 luni, 18 luni, 30 luni şi 4 ani, am aplicat părinţilor testelele ASQ 3+, respectiv ASQ – SE (Ages & Stages Questionnaires®, Brookes Publishing) şi le-am solicitat să răspundă cât mai obiectiv la itemii acestor chestionare pentru propriul copil.

Aceste teste screening sunt utilizate pe scară largă în Statele Unite, la nivelul asistenţei medicale primare, fiind un instrument de apreciere a dezvoltării neuropsihice la copil bazat pe interviul părinţilor (3-6). Sunt alcătuite din mai multe seturi de întrebări specifice pentru diferite etape de vârstă (pot fi testaţi copii între 1 şi 66 de luni) şi permit evaluarea la nivelul comportamentului verbal, motor, cognitiv şi social-afectiv. Itemii calculaţi încadrează copiii în trei categorii: dezvoltare neuropsihică în parametrii vârstei, dezvoltare la limită şi tulburare în dezvoltare care necesită asistenţă specializată. Academia Americană de Pediatrie consideră că acest test de screening are cel mai bun raport cost–beneficiu (7) iar implicarea părinţilor în supravegherea şi stimularea dezvoltării neuropsihice a copiilor are o importanţă deosebită întrucât aceştia, bine informaţi, se dovedesc capabili să ofere cele mai bune detalii (8).

Pentru efectuarea screeningului a fost întocmit un chestionar în care s-au consemnat datele generale şi medicale legate de evoluţia copilului, particularităţi ale vieţii de familie, stilul comportamental parental, metode de stimulare a dezvoltării neuropsihice utilizate de către părinţi.

După aplicarea screeningului, rezultatele au fost discutate cu familia. În condiţiile în care punctajele obţinute au fost la limită pe unul sau mai multe domenii de comportament, am recomandat stimulare şi am recurs la repetarea testului peste un interval de 1-2 luni. În cazurile în care punctajele au fost sub limita vârstei, pe cel puţin 1 domeniu de comportament, am recomandat evaluare de specialitate (pediatru, psihiatru, neurolog, psihilog, după caz).

Este importantă examinarea copiilor în condiţii optime şi realizarea unei bune comunicări cu părinţii acestora care pot fi îngrijoraţi în legătură cu rezultatele testării. Medicul trebuie să se asigure că familia a înţeles raţiunea şi utilitatea testului şi mai ales faptul că nu este un test diagnostic.

Prelucrarea şi interpretarea datelor acumulate s-a realizat prin metode descriptive, analitice şi statistică matematică (pragul de semnificaţie 95%, testele χ^2 şi *t-Student*).

REZULTATE ŞI DISCUŢII

1. *Caracteristicile lotului de studiu.* Lotul de 324 copii a fost omogen în ceea ce priveşte mediul de proveniență urban şi distribuţia pe sexe 163 băieţi (50,30%) şi 161 fetiţe (49,7%).

Vârsta părinţilor variază pentru mame între 20 – 39 de ani şi pentru taţi între 20 – 60 ani. Vârsta medie a mamei a fost semnificativ mai mică decât a tatălui (t-Student = 7,39; GL=646; p<0,001). Din familii cu nivel de trai mediu au provenit 85,8% dintre copii iar 66,7% au ambii părinţi cu studii superioare. Numărul de copii ai unei familii a fost invers proporţional cu nivelul de trai şi cu gradul de educaţie al părinţilor. Majoritatea familiilor de intelectuali au un singur copil (χ^2=15,58; GL=2; p=0,0004) şi o preocupare mai mare a mamei pentru carieră (χ^2=16,04; GL=2; p=0,0003).

2. *Depistarea tulburărilor în dezvoltarea neuropsihică a copiilor* s-a ameliorat prin utilizarea chestionarelor individuale adresate părinţilor. Comparativ cu evaluarea uzuală, prin aplicarea screeningului ASQ am identificat încă 72 de copii cu întârzieri în dezvoltare, mai ales din rândul celor necooperanţi, la care examenul clinic a fost constant dificil. Diferenţa dintre metode a fost semnificativă statistic (χ^2= 40,77; GL=2; p<0,001) (tab. I).

Analizând întârzierile în dezvoltare pe domenii comportamentale am observat că

cele mai frecvente s-au înregistrat la nivel social-afectiv şi verbal (limbajul expresiv), urmate de cele din domeniul cognitiv. Învăţarea limbajului este un proces dependent psiho-emoţional, 21 dintre copiii care au necesitat asistenţă de specialitate pentru dificultăţile de comunicare având şi diverse tulburări în dezvoltarea social-afectivă (fig. 1).

TABELUL I

Gradul de depistare al întârzierilor în dezvoltarea neuropsihică a copiilor în funcţie de metoda de examinare utilizată

Lot 324 copii	Dezvoltare în parametrii vârstei		Dezvoltare la limită		Întârzieri în dezvoltare care necesită asistenţă de specialitate		Semnificaţie statistică
	Nr.	%	Nr.	%	Nr.	%	
Evaluarea uzuală	246	75,9	45	13,9	33	10,2	χ^2=40,77; GL=2; p<0,001
Aplicarea testelor screening	174	53,7	111	32,4	39	12	

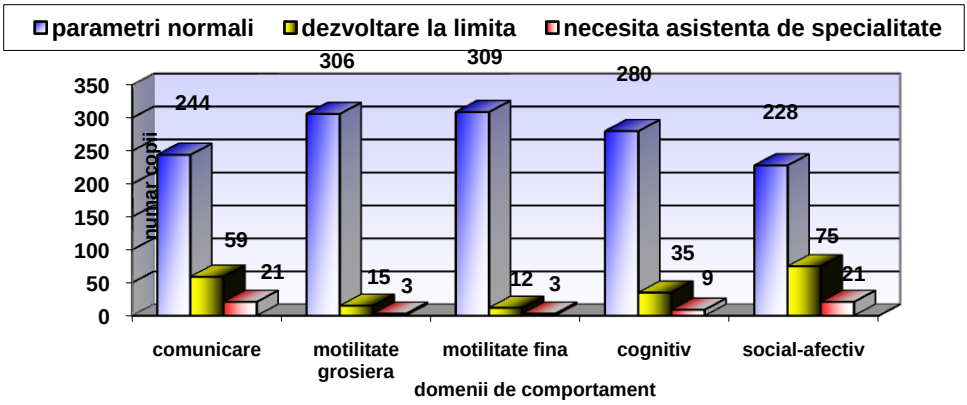

Fig. 1. Dezvoltarea neuropsihică pe domenii comportamentale a celor 324 de copii din lotul de studiu

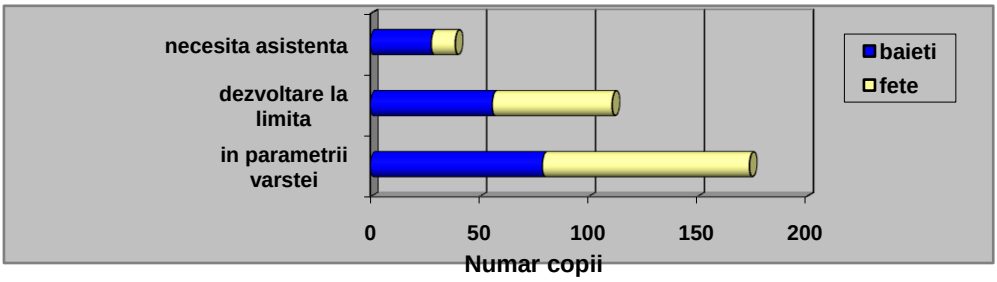

Fig. 2. Dezvoltarea neuropsihică la cei 163 de băieţi şi 161 de fete din lotul studiat

În lotul nostru, frecvenţa tulburărilor în dezvoltare care necesită asistenţă specializată, a fost de 12% (39 copii din 324), comparabilă cu 11,7% înregistrată în singurul studiu naţional efectuat în ultimii 25 de ani, proiectul CENTAUR (9). În grupul copiilor cu dizabilităţi am constatat o predominanţă a băieţilor (28 de băieţi faţă de 11 fetiţe), mai ales în ceea ce priveşte dezvoltarea achiziţiilor verbale şi social-afective (fig. 2).

Diferenţele înregistrate între sexe au fost semnificative statistic (χ^2=8,88; GL=2; p=0,012) şi concordă cu datele din literatură care arată o afectare mai crescută a băieţilor comparativ cu fetele, cu o rată de 4/1 pentru tulburările din spectrul autist şi de 7/3 sau chiar mai mare, în cazul ADHD (10).

Incidenţa tulburărilor din spectrul autist în lotul nostru a fost de 0,6% (2 băieţi din 324 copii), comparabilă cu frecvenţa actuală raportată în studiile internaţionale (0,2-0,7%) (11). Frecvenţa ADHD (Attention Deficit Hyperactivity Disorder) a fost de 0,9% (3 băieţi din 324 copii), valoare apropiată de cea raportată în studiul efectuat în 2005, de către Doina Felea şi colab. care arată o incidenţă de 1,1% a acestei afecţiuni la grupa de vârstă 0-6 ani (10). Cei cinci copii au fost suspectaţi prin evaluarea uzuală, confirmaţi prin testele screening aplicate şi sunt incluşi în prezent în programe terapeutice specifice, iar beneficiile au devenit vizibile.

Complianţa familiilor în ceea ce priveşte efectuarea consultaţiilor prevenţionale a fost foarte bună la 92% dintre copii, doar în 27 de cazuri (8%) au existat uneori dificultăţi de comunicare, reflectate şi în promptitudinea cu care aceştia au răspuns la chestionarele adresate. După aplicarea testelor screening am constatat o creştere semnificativă a ponderii întrebărilor adresate de către părinţi în legătură cu dezvoltarea neuropsihică a copiilor; practic procentul s-a dublat (de la 55,2% la 100%).

Prin testele screening am descoperit copii cu întârzieri în dezvoltare datorită stimulării deficitare şi cu tulburări de comportament determinate de o abordare educaţională neadaptată temperamentului copilului.

3. *Evaluarea şi consilierea de specialitate* a fost recomandată la 132 de copii (40,7%). Au fost evaluaţi 97 (73,5%), rezultatele testului screening aplicat s-au confirmat la 90 dintre aceştia (93%). Menţionăm că în unele cazuri, mai ales în cele problemă, părinţii au refuzat la început să accepte ideea că ar putea exista o tulburare în dezvoltarea propriului copil şi doar atunci când aceasta s-a agravat şi a devenit vizibilă pentru un nespecialist, au decis să se adreseze medicului, fiind întârziată precizarea diagnosticului şi integrarea într-un program terapeutic adecvat.

Pe durata efectuării cercetărilor s-a constatat o accesibilitate redusă a pacienţilor la testarea şi consilierea psihologică. În sistemul de asigurări de sănătate din România, serviciile menţionate nu sunt gratuite, motiv pentru care, datorită dificultăţilor financiare, puţine familii şi-au permis să utilizeze serviciile de parenting sau să apeleze la consiliere psihologică legată de dezvoltarea copilului lor. În ceea ce priveşte tratarea şi recuperarea unui copil diagnosticat cu tulburare pervazivă de dezvoltare, părinţii au posibilitatea să acceseze servicii parţial compensate. Datorită complexităţii terapiei, mama este obligată să fie tot timpul în preajma copilului, ea trebuie să renunţe la serviciu, la cariera personală, motiv pentru care veniturile familiei scad. Această realitate este confirmată şi de ultimul studiu efectuat de către Norra MacReady "Autism Often Associated With Loss of Family Income" (12), care arată că familia unui

copil autist este supusă unui dublu stres, atât emoţional cât şi financiar. Un copil cu autism necesită o terapie complexă care implică cel puţin 5 specialişti, mama este angajată în recuperarea copilului său, într-o muncă "full-time", nerecompensată financiar ci doar prin satisfacţia de a observa progresele copilului.

Luând în considerare criteriile de selecţie ale subiecţilor studiului şi faptul că majoritatea provin din familii cu condiţii de viaţă bune, numărul total al copiilor cu întârzieri în dezvoltare este ridicat, mai ales în ceea ce priveşte comportamentul verbal şi achiziţiile cognitive. Această situaţie ar putea fi legată de caracteristicile vieţii de familie din România unde, părinţii copleşiţi de obligaţiile zilnice îşi petrec din ce în ce mai puţin timp cu copiii, acordând atenţie mai mult nevoilor fiziologice ale acestora şi neglijându-le pe cele psihologice.

CONCLUZII

1. Nivelul de depistare al tulburărilor în dezvoltarea neuropsihică a copiilor a crescut prin utilizarea chestionarelor individuale adresate părinţilor, iar deficienţele identificate au fost confirmate de evaluările ulterioare de specialitate.

2. Testele screening ASQ, accesibile atât pentru părinţi cât şi pentru medic, prezintă avantajul că nu prelungesc durata consultaţiei şi asigură o deschidere spre comunicarea mai bună cu familia.

3. Experienţa dobândită prin aplicarea acestui screening de apreciere a dezvoltării neuropsihice la copil poate fi utilă pentru introducerea unor teste standardizate şi adaptate pentru a fi folosite în practica medicului de familie din România.

SELF-NEGLECT IN THE ELDERLY: WHERE ARE WE NOW? (Abstract): Self-neglect in an elderly person is a behavior that threatens his/her own health and safety. It is present when a person refuses to adequately feed, water, shelter, or clothe himself, refuses medication or medical care, and personal safety measures. **Material and method:** This is a multicentric study of self-neglect in three geriatric units from Finland, Greece and Romania The medical, social, psychological and behavioral profile analysis was based on a questionnaire; this questionnaire relied on existing studies and social, economic and medical facts in the three countries. The cognitive function, nutritional status, and the presence or absence of depression have also been assessed. **Results and discussions:** The data obtained until now support the importance of self-neglect among the elderly. The social-medical network should not only identify, diagnose, prevent, and treat the elderly affected by the phenomenon of self-neglect, but also educate the society to help them and, moreover, to prevent their marginalization. **Key words:** SELF-NEGLECT, ELDERLY, ABUSE

Demographic prognoses shows that world population is in a continuing process of ageing. In 2006, almost 500 million people worldwide were aged 65 and older. By 2030, this figure is expected to increase up to 1 billion, 1 in every 8 of the earth's inhabitants being an elderly-aged. Europe and Romania follow the same trend: in the case of the latter, the elderly population will increase by 58 million - i.e. 77% - till 2050.(1) EUROPOP2008 convergent scenario shows that in 2030 Romania will have a total population of 20 million, of which over 4 million (20%) will be elderly, with one million being of forth age. Estimates show that in 2060, Romania will have a third of its population aged over 65 (i.e. 35%) (2).

In this context, both society and medical services will increasingly confront themselves with problems and disorders that are specific to the elderly. Elderly self-neglect is one of them, since its increasing incidence it is already considered a big concern for medical services, social services, family and community.

The phenomenon of self-neglect has been subject of documentation over centuries, but it was first officially described in 1966 as the „Senile Breakdown Syndrome" or Diogenes Syndrome. This term refers to cases of severe self-neglecting with mental

illnesses, personality disorders, being also identified in the case of the youngsters. In the late 70's the term „self-neglect" came into use. Nowadays self-neglect is recognized in various countries, including in some of the European Union, as a form of elder abuse; in the United States it is mentioned in the Older Americans Act Amendments of 1987 (3-7).

Self-neglect is a multifactorial behavioral entity through which the elderly threatens their own safety or health and it is described in a person who can't provide for his/herself adequate food, water, clothing, shelter, personal hygiene, medication, safety precautions and social needs. This behavior is considered to be caused by mental, social, economical and physical disturbances, and thus is expected to promote and exacerbate such disturbances.(8) In the United States, elder self-neglect represents half or more of all cases reported to adult protective services and their number is in constant growth.(9) Incidence rate of 23/1000 is estimated to be similar to the incidences of new onset diabetes, and cataracts in the elderly and affect 3-8% of elderly population. Despite the fact that self-neglect is a factor in the rising necessity of the elderly institutionalization, it is also a marker in the growth of the mortality rate, regardless of the cognitive function or the physical shape (10-13).

MATERIAL AND METHOD

Given the lack of substantial data regarding the phenomenon of elderly self-neglect in Europe, we initiated a comparative study of elderly people falling into the incidence of the self-neglect, in terms of medical, social, economic, psychological and behavior. This prospective study was launched in 2010 and is currently ongoing in three geriatric clinics in Finland, Greece and Romania. The enrolled patients were selected from the elderly who presented themselves in the emergency room of the "Dr. C. I. Parhon" Hospital of Iasi with various acute problems; they were brought in by family, neighbors, acquaintances or ambulance crew. The subjects showed either decompensate chronic diseases or signs of severe self-neglect: severe malnutrition, severe dehydration with electrolytes imbalance, pressure sores, and insect infestations. Patients were eligible for the study if they met at least one of following criteria:

1. Persistent neglect of self-hygiene or home environment;
2. Repeated refusal of one/all services indicated for improving quality of life;
3. Self-endangerment through manifestation of unsafe behaviors (e.g. persistent refusal to treat a wound, creating life-hazards in the home, alcohol abuse).

On the basis of the current legislation, as well as a series of data from the medical literature, and socio-economical, medical, psychological and behavioral realities from the three participating countries, we conceived a questionnaire that was conducted by every participant. We also assessed the cognitive function, the nutritional status and the presence or absence of depression.

Through the first part of the questionnaire, we collected data with regards to the **socio-demographic component** of the geriatric assessment: age, gender, educational level, income, presence or absence of familial support and living conditions (alone or in company).

The second part of the questionnaire contains data on **patients' personal hygiene**:

- general aspect and general hygiene status;
- skin aspect: clean, dirty, dry, the presence of bruises, pressure sores, insect bites:
- skin appendages aspect: nails (clean / dirty, trimmed/long) and hair (clean, dirty,

combed, pediculosis);

- oral cavity aspect including teeth;
- clothes aspect: clean/soil, torn, stains / smells of feces or urine

These data were collected upon arrival of the patients by our clinics medical personnel participating in the study, and reviewed upon subsequent evaluations during hospitalization.

As part of the comprehensive geriatric evaluation, were evaluated the following indicators: **cognition -** by performing Mini Mental State Examination (MMSE), adapting scores according to educational level, presence of motor imbalance, visual or hearing deficit; **nutritional status -** by collecting data from patients or caregivers and completing the Mini Nutritional Assessment (MNA©); and **mental status –** evaluating the presence of depression by completing the Geriatric Depression Scale (GDS-4). The medical personal enrolled in the study submitted these standardized tests. A number of elderly patients could not complete the entire battery because of inability or unwillingness.

Another part of the self-neglect evaluation is represented by the data about **living conditions and household**. Related to this aspect, our questionnaire includes a series of questions addressed to the caregiver, if applicable. In some cases these questions were answered by the ambulance crew who attended the patient to the hospital. The questions about environment conditions were developed on the basis of the following issues:

- general household condition;
- the detailed aspect of all rooms including the garden and the yard (if applicable): neat/ squalor, mess, deteriorated furniture, drapers/carpets/sheets torn, human/animal waste;
- aspect of walls, sealing, windows;
- presence or functionality of household utilities (electrical installation, sanitation, gas);
- presence / absence of insects in the house or pets' living condition (if applicable)

The evaluation continues with the **chronic medical conditions.** The data were collected directly from the patient or, when this was not possible, from caregivers, previous medical documentation or previous admissions. In the presence of co morbidities, we evaluated the medication, the compliance with the treatment and the possible need to use different types of aids (hearing, dentures, eyeglasses, walkers, wheelchairs, etc.).

The last part of the questionnaires consists in questions witch evaluate if the elderly are aware of their self-neglect state, if this bothers them and, to include all data we acquired, is aimed at identifying the main cause of the phenomenon of self-neglected on the evaluated subjects.

The study' results will be centralized and completed by the Finnish partners of the project.

RESULTS AND DISCUSSION

The partial obtained data confirm the importance of self-neglect among the elderly, especially as it accompanied by the low capacity to perform activities of daily living, this leading to a poor personal hygiene, an insufficient care of the home environment, a neglect of medical conditions and the lack of treatment for them. The problem is more important as it has been demonstrated that the self-neglect thus reported and confirmed is associated with increased mortality, especially in the first year of diagnosis. This aspect has direct implications on social and medical services which should identify and intervene at an early stage in the cases of self-neglect of the elderly.

The intervention team must be complex, multidisciplinary, specialized in elderly problems and should include geriatrics,

psychologists, nurses, family doctor, social services assistant, lawyers and especially family and community)(12-16).

The measures to be applied in order to help the elderly self-neglect should consider several ethical issues:

- the people's right to autonomy but, at the same time, the obligation of the society and the medical services to act as to ensure the patients' well-being;
- the assessment of the decisional capacity, taking into account the clinical and the legal aspects with secondary implications;
- the situation in which the self-neglected elderly, through their conduct, put themselves and the others in danger

Taking these aspects in account, the social-medical network must act not only to identify, diagnostic, prevent and treat the elderly affected by the phenomenon of self-neglect, but also to educate the society which should help them and moreover, avoid marginalizing them.

PERITONITA BACTERIANĂ SPONTANĂ: COMPLICAŢIE SEVERĂ A CIROZEI HEPATICE – STUDIU PROSPECTIV

Gabriela Balan, Anca Trifan, D. Botezatu, Carmen Anton
Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
Institutul de Gastroenterologie şi Hepatologie

SPONTANEOUS BACTERIAL PERITONITIS: A SEVERE COMPLICATION OF LIVER CIRRHOSIS (Abstract): Spontaneous bacterial peritonitis (SBP) is a frequent and severe complication of decompensated cirrhosis. SBP is defined as an infection of initially sterile ascitic fluid (AF) without a detectable, surgically treatable source of infection. **Aim:** to evaluate the prevalence, incidence, pathogens and clinical outcome of patients with liver cirrhosis and SBP. **Methods:** a prospective study evaluated 34 episodes of SBP developed in 29 patients with cirrhosis and ascites admitted in hospital. SBP was diagnosed based on a polymorphonuclear cell count in ascitic fluid of >250 cells/mm^3 in the absence of data compatible with secondary peritonitis. **Results:** The mean age of the group was 56.89 ± 8.79 years, more frequently occurred in men 21 of 29 cases (72.41%). Microorganisms were isolated in 12 episodes (35.29%): Gram-negative bacteria in 8 (66.67%) and Gram-positive in 4 (33.33%). The first-line treatment failure and in-hospital mortality rates were 26.47% and 17.64%, respectively. The low in-hospital mortality seems to be related to earlier diagnosis and treatment. In the multivariate analysis, three significant independent predictive factors of in-hospital mortality were identified: a high Model of End-Stage Liver Disease (MELD) score, renal failure and SBP caused by extended-spectrum â-lactamase-producing organisms. The relapse rate of PBS was 21.73%. **Conclusions:** SBP remains to be a serious complication, especially in patients with a high MELD score. Ceftazidim represents a good choice in empirical treatment of SBP. **Key words:** LIVER CIRRHOSIS, PERITONITIS, TREATMENT, PROGNOSIS

Termenul de peritonită bacteriană spontană (PBS) a fost introdus în 1971 de către Conn şi Fessel, PBS fiind definită ca infecţia spontană a lichidului ascitic în absenţa identificării oricărei surse infecţioase intraabdominale (1).

Ciroza hepatică (CH) se caracterizează printr-o susceptibilitate crescută la infecţii datorită deficienţelor mecanismelor de apărare ale organismului. PBS este cea mai frecventă infecţie la bolnavii cirotici, urmată de infecţiile tractului urinar (20%), pneumonie (15%) şi bacteriemie (12%) (2). Recunoscută ca o complicaţie frecventă şi severă, PBS apare la 8-27% din pacienţii cirotici cu ascită spitalizaţi (3).

Supravieţuirea acestor bolnavi depinde de precocitatea diagnosticului şi tratamentului şi de instituirea profilaxiei secundare a PBS. Având în vedere că PBS poate evolua asimptomatic sau insidios, se recomandă efectuarea paracentezei diagnostice în toate cazurile de CH cu ascită şi când apar manifestări clinice sugestive precum durerile abdominale, febra, encefalopatia hepatică, agravarea disfuncţiei renale sau hepatice (4). Prezenţa în lichidul de ascită a peste 250 neutrofile/mm^3 semnifică suprainfecţia

bacteriană a acestuia (PBS).

Tratamentul antibiotic empiric trebuie început imediat ce diagnosticul a fost stabilit, înainte de a se cunoaşte agentul etiologic şi sensibilitatea *in vitro* (4). Bacteriile cel mai frecvent identificate în 65% din cazurile cu culturi pozitive sunt bacteriile Gram-negative din familia *Enterobacteriaceae*, în special *Escherichia coli* şi *Klebsiella pneumoniae*. Restul agenţilor microbieni sunt reprezentaţi de cocii Gram-pozitivi (5). Cefalosporinele de generaţia a III-a (cefotaxim, ceftriaxona, ceftazidim) şi combinaţia amoxicilină-acid clavulanic, reprezintă antibioticele de primă intenţie în tratamentul PBS.

Prognosticul pe termen lung al bolnavilor cu PBS este nefavorabil. Rata recurenţei PBS în primul an este de 40-70%, iar supravieţuirea la 1 an şi la 2 ani, după un episod de PBS este de aproximativ 30-40%, respectiv 20% şi chiar mai scăzută la pacienţii cu scor Child-Pugh peste 10 (6). Profilaxia PBS este indicată la următoarele 3 categorii de pacienţi cirotici: antecedentele de PBS, bolnavii spitalizaţi pentru hemoragie digestivă superioară şi cei cu conţinut scăzut de proteine în lichidul de ascită. Utilizarea pe termen lung a antibioticelor cu spectru larg poate determina creşterea numărului microorganismelor rezistente la antibiotice cu implicaţii considerabile asupra managementului şi tratamentului PBS, conducând la necesitatea reevaluării ghidurilor terapeutice actuale (6).

Scopul studiului prezent de a evalua trăsăturile clinice şi prognosticul bolnavilor cu ciroză hepatică complicată cu PBS internaţi în Clinica de Gastroenterologie a Spitalului Clinic Judeţean de Urgenţă „Sfântul Apostol Andrei" Galaţi.

MATERIAL ŞI METODĂ

Studiul prospectiv a inclus 122 bolnavi cu CH şi ascită internaţi în Clinica de Gastroenterologie a Spitalului Clinic Judeţean de Urgenţă „Sfântul Apostol Andrei" Galaţi în perioada 1 ianuarie 2007-31 decembrie 2007 şi monitorizaţi pe o perioadă de 36 luni. Diagnosticul CH s-a stabilit pe baza criteriilor clinice, ecografice şi histologice. Severitatea cirozei hepatice s-a apreciat folosind scorurile Child-Pugh şi MELD (model for end-stage liver disease). Scorul MELD s-a calculat utilizând formula: 9,57 x log e (creatinina, mg/dl) + 3,78 x log e (bilirubina, mg/dl) + 11,2 x log e (INR) + 6,43.

Bolnavii au fost evaluaţi anamnestic, clinic, biologic (teste standard de laborator, incluzând hemoleucograma, teste biochimice hepatice şi renale, indice de protrombină, examen de urină) şi imagistic (ecografie abdominală, radiografie toracică). Paracenteza diagnostică şi cultura lichidului de ascită s-au efectuat la internarea pacienţilor şi în cazul apariţiei în cursul spitalizării a simptomelor şi semnelor sugestive pentru PBS (febră, dureri abdominale, alterarea statusului mintal, hipotensiune arterială, deteriorarea funcţiei renale, leucocitoză) în absenţa altor factori precipitanţi identificabili. Lichidul de ascită s-a recoltat în recipiente sterile, respectând condiţiile de asepsie. În fiecare recipient cu mediu de cultură MacConkey agar s-au inoculat cel puţin 10 ml de lichid de ascită, iar bacteriile identificate prin cultură au fost testate pentru sensibilitate la antibiotice prin metoda difuziunii.

Diagnosticul PBS s-a stabilit prin evidenţierea în lichidul de ascită a peste 250 PMN / mm^3 în absenţa semnelor clinice şi radiologice de peritonită bacteriană secundară. Peritonita bacteriană secundară se defineşte prin identificarea în lichidul de ascită a două sau mai multe microorganisme sau asocierea PMN $>$ 250 /mm^3 lichid ascită cu cel puţin doi din următorii trei parametri: glucoza $<$ 50 mg/dl, proteine totale $>$ 1g/dl şi lactat dehidrogenaza (LDH) peste limita superioară a normalului a LDH seric.

Bolnavii cu PBS au primit tratament empiric cu Ceftazidim (cefalosporină de gene-

TABELUL I
Caracteristicile lotului studiat

Vârsta (ani)	56,89±8,79
Bărbaţi/Femei	21/8
Cauza cirozei, n (%)	
Consum de alcool	20 (68,96)
Virus hepatitic C	10 (34,48)
Virus hepatitic B	8 (27,58)
Clasa Child-Pugh (media ± DS)	11,68 ± 2,28
Scorul Child-Pugh, n (%)	
Clasa Child B	7 (24,14)
Clasa Child C	22 (75,86)
Scorul MELD	21,8 ± 7,4
Manifestări clinice, n (%)	
Febră	18 (52,94)
Dureri abdominale	14 (41,17)
Greaţă/vărsături	7 (20,58)
Encefalopatie hepatică	10 (29,41)
Hemoragie gastro-intestinală	6 (17,64)

raţia a III-a) intravenos, 1-2g/12 ore, minimum 5 zile, întrucât aceasta a reprezentat opţiunea terapeutică disponibilă pe perioada spitalizării, studiile indicând o eficienţă similară cu a cefotaximului. Doza antibioticului a fost ajustată conform funcţiei renale pe perioada tratamentului. În cazurile cu eşec terapeutic la antibioticul iniţial, tratamentul a fost adaptat conform antibiogramei sau empiric.

Paracenteza diagnostică s-a repetat după 48 ore de la începerea antibioterapiei pentru stabilirea eficienţei acesteia. Lipsa de răspuns la tratament s-a considerat în cazurile ce au prezentat alterarea stării generale, scăderea PMN < 25% faţă de valoarea iniţială, menţinerea culturilor pozitive după 48 ore de antibioterapie sau care au decedat înaintea repetării paracentezei. Vindecarea PBS s-a apreciat în condiţiile remiterii tuturor semnelor clinice de infecţie, scăderii PMN în lichidul de ascită < 250/ mm^3, normalizării leucocitelor în sângele periferic şi negativării culturilor din lichidul de ascită. Bolnavii care au primit chinolone p.o. mai mult de o lună înaintea episodului de PBS au fost incluşi în grupul cu antibioticoprofilaxie. Mortalitatea intraspitalicească a fost definită ca deces de orice cauză în cursul spitalizării.

Datele au fost exprimate ca medie ± deviaţie standard (DS). Pentru compararea grupurilor s-au utilizat testele *t-student* (pentru date cantitative) şi χ^2 (pentru date calitative). Prin analiză univariată au fost identificaţi factorii predictivi ai mortalităţii intraspitaliceşti. Variabilele analizate au fost vârsta, sexul, cauza cirozei, PBS, datele clinice şi de laborator efectuate (inclusiv scorurile Child-Pugh şi scorul MELD). Variabilele cu semnificaţie statistică ($p < 0,05$) la analiza univariată au fost folosite la analiza multivariată, aplicându-se analiza regresivă logistică binară „step-wise" pentru identificarea factorilor predictivi ai supravieţuirii. În scopul determinării semnificaţiei datelor la analiza multivariată s-a utilizat intervalul de încredere (IC) de 95%, valoarea $p < 0,05$ fiind considerată statistic semnificativă. Datele au fost prelucrate folosind programul *SPSS 17.0*.

REZULTATE

Studiul a inclus 34 episoade de PBS dezvoltate de 29 pacienţi (21 bărbaţi şi 8 femei) din cei 122 bolnavi cu CH şi ascită internaţi în clinică, stabilindu-se o prevalenţă a PBS de 23,77%. Caracteristicile demografice şi

clinice ale cazurilor selectate la momentul diagnosticului PBS sunt prezentate în tabelul I. Vârsta medie a fost 56,89±8,79 ani, iar sexul masculin a fost predominant (72,41%). Consumul de alcool a reprezentat cauza cea mai frecventă a CH (68,96%), urmat de infecţia cu virus hepatitic C (34,48%) şi virus hepatitic B (27,58%). Din punct de vedere al clasificării Child-Pugh, a predominat clasa Child C (75,86%), urmată de Child B (24,14%); nici un bolnav nu s-a situat în clasa Child A. Scorul MELD mediu a fost de 21,8 ± 7,4. Majoritatea cazurilor cu PBS au fost simptomatice, febra şi durerile abdominale, fiind cel mai frecvent întâlnite în 18 cazuri (52,94%), respectiv 14 cazuri (41,17%). Encefalopatia hepatică la momentul diagnosticului PBS a fost prezentă în 10 cazuri (29,41%) şi ca simptom unic al PBS în 3 cazuri (8,82%), iar insuficienţa renală în 13 (38,23%) din cazuri. Identificarea factorilor de risc pentru apariţia PBS a fost posibilă în 14 cazuri: 5 cazuri cu antecedente de PBS (4 dintre acestea având antibioticoprofilaxie pentru PBS la momentul internării), 6 cu hemoragie digestivă superioară şi 3 cu proceduri invazive (tab. I).

Cultura pozitivă din lichidul de ascită s-a înregistrat în 12 (35,29%) din cele 34 de cazuri de PBS. Bacteriile Gram-negative (BGN) au reprezentat 66,67% din totalul germenilor identificaţi (8 din 12 cazuri). *Escherichia coli* a fost cel mai frecvent întâlnită (5 cazuri, 41,66%), urmată de *Klebsiella pneumoniae* (3 cazuri, 25%). Cocii Gram-pozitivi au fost prezenţi în 4 cazuri (33,33%) (2 *Streptococcus pneumoniae*, 1 *Staphylococcus aureus* şi 1 *Enterococcus faecalis*). Comparând grupurile de PBS determinate de bacterii Gram-pozitive şi Gram-negative s-a constatat că distribuţia pacienţilor nu a fost semnificativ diferită în ceea ce priveşte scorul Child-Pugh ($p = 0,083$) şi mortalitatea intraspitalicească ($p = 0,246$), însă scorul MELD, leucocitele, PMN şi proteinele din lichidul de ascită (LA) au fost semnificativ diferite între cele 2 grupuri ($p = 0,042$, 0,026, 0,029 şi, respectiv, 0,027). În acelaşi timp, scorurile Child-Pugh şi MELD au prezentat valori mai reduse în cazurile de PBS cu bacterii Gram-pozitive (BGP) (tab II).

Testarea sensibilităţii *in vitro* a bacteriilor a arătat că 5 bacili Gram-negativi (62,5%) au fost rezistenţi la Ampicilină şi 2 (25%) la Ciprofloxacin. Rezistenţa la Ceftazidim s-a înregistrat în 4 cazuri (2 *Escherichia coli*, 1 *Klebsiella pneumoniae* şi 1 *Enterococcus faecalis*), identificate ca fiind bacterii producătoare de beta-lactamază cu spectru extins (BLSE), sensibile, însă, la Imipenem şi Meropenem.

Tratamentul empiric cu Ceftazidim s-a început în 26 cazuri (76,47%). În celelalte 8 cazuri, s-a folosit un alt antibiotic întrucât: 6 au dezvoltat PBS în pofida tratamentului cu cefalosporine iniţiat în scop profilactic înaintea procedurilor invazive sau pentru HDS), iar 2 pacienţi prezentau alergie la cefalosporine. Antibioticele de primă linie au fost administrate timp de 9±4 zile. Răspunsul la tratament s-a constatat în 19 cazuri tratate iniţial cu Ceftazidim (73,07%), în timp ce în 5 cazuri (19,23%) a fost necesară schimbarea terapiei empirice datorită scăderii cu < 25% a PMN în lichidul de ascită la paracenteza efectuată după 48 ore de la începerea antibioterapiei. În aceste cazuri, tratamentul antibiotic a fost schimbat cu Imipenem în 4 cazuri şi Ciprofloxacin într-un caz. În cele 5 cazuri cu eşec terapeutic la Ceftazidim bacteriile identificate au fost fie rezistente la Ceftazidim (4 producătoare de BLSE – 2 *Escherichia coli*, 1 *Klebsiella pneumoniae* şi 1 *Enterococcus faecalis*), fie au avut o sensibilitate redusă la Ceftazidim (*Staphylococcus aureus*). Dintre bolnavii care au primit ca tratament de primă intenţie Ceftazidim, 2 au decedat înaintea începerii antibioterapiei de linia a doua, iar doi în decurs de 72 ore după schimbarea tratamentului antibiotic.

Eşecul la tratamentul empiric s-a produs în 9 cazuri (26,47%): 7 cazuri tratate cu

Ceftazidim, un caz tratat cu Ciprofloxacin şi un caz tratat cu Amoxicilină-acid clavulanic. Analiza multivariată a identificat scorul MELD la internare (p = 0,027) şi PBS produse de bacterii producătoare de BLSE (p = 0,004) ca factori predictivi independenţi pentru eşecul tratamentului antibiotic empiric. Remiterea PBS s-a obţinut în 22 din 26 cazuri tratate iniţial cu Ceftazidim (84,61%), 4 bolnavi decedând. Decesul a survenit în 2 din cele 8 cazuri care au primit ca tratament de primă linie un antibiotic diferit de Ceftazidim. Mortalitatea intraspitalicească a fost de 17,64%. Cauzele deceselor au fost reprezentate de: hemoragie digestivă superioară (3 cazuri), sindrom hepato-renal (2 cazuri) şi encefalopatie hepatică (comă) 1 caz. Pe parcursul perioadei de monitorizare recurenţa PBS s-a produs în 5 cazuri (21,73%) din cei 23 bolnavi ce au supravieţuit primului episod de PBS şi care au beneficiat de profilaxie secundară antibiotică cu chinolone.

La analiza multivariată variabilele independente în relaţie cu mortalitatea în PBS au fost insuficienţa renală (creşterea azotului ureic şi/sau creatininei serice peste 30 mg/dl, respectiv, 1,5 mg/dl) (p= 0,038), scorul MELD la internare (p = 0,017) şi PBS cu bacterii producătoare de BLSE (p = 0,026).

DISCUŢII

Scopul studiului prospectiv a fost de a evalua trăsăturile clinice actuale, răspunsul terapeutic şi prognosticul cirozelor hepatice complicate cu PBS internate în Clinica de Gastroenterologie din Spitalul Judeţean Galaţi. Aceasta analiză este justificată de modificările din ultimii ani referitoare la tipul şi etiologia infecţiilor bacteriene în ciroza hepatică (7, 8, 9). Pentru aceasta, studiul a evaluat un grup de pacienţi cu ciroză hepatică cu ascită complicată cu PBS, care au fost monitorizaţi timp de 36 luni.

Rezultatele studiului susţin recomandările ghidurilor actuale privind stabilirea diagnosticul PBS prin numărarea PMN în lichidul de ascită şi iniţierea tratamentul empiric cu cefalosporine de generaţia a III-a (în studiul prezentat Ceftazidim), avându-se

în vedere necesitatea schimbării antibioticului doar în 19,23% din cazuri. Ca urmare, Ceftazidimul poate fi considerat ca opţiune terapeutică în PBS, prezentând o eficienţă similară cu a cefotaximului - antibioticul recomandat de ghidurile actuale ca tratament de primă intenţie a PBS.

Cazurile cu eşec terapeutic la Ceftazidim datorat fie bacteriilor producătoare de BLSE (*Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus faecalis*), fie sensibilităţii bacteriene reduse la Ceftazidim (*Staphylococcus aureus*) au avut un prognosticul rezervat, cu o rată crescută de mortalitate (50%). Aceste date indică prezenţa bacteriilor producătoare de BLSE ca fiind un factor predictiv independent pentru eşecul terapeutic şi mortalitatea intraspitalicească. Bacteriile producătoare de BLSE au fost rezistente la toate antibioticele, cu excepţia Imipenem şi Meropenem. Ca urmare, în condiţiile identificării prin cultură a bacteriilor producătoare de BLSE sau al eşecului terapeutic la administrarea de cefalosporine de generaţia a III-a, ar trebui avută în vedere înlocuirea antibioticului iniţial cu Imipenem sau Meropenem.

Diagnosticul precoce al PBS, iniţierea tratamentului antibiotic empiric şi adaptarea ulterioară a acestuia conform rezultatelor antibiogramei a permis controlul eficient al infecţiei şi reducerea mortalităţii intraspitaliceşti la 17,64%, rezultatele fiind în concordanţă cu datele din literatura de specialitate (10).

În acest studiu, prezenţa la internare a disfuncţiei renale şi scorul MELD au fost identificaţi ca factori predictivi independenţi ai mortalităţii în PBS, rezultate similare fiind raportate de alte studii (11, 12). Pe de altă parte, aceşti factori se corelează, de obicei, cu prezenţa unei insuficienţe hepatice avansate.

Datele din literatură indică o incidenţă în creştere a bacteriilor Gram-pozitive implicate în etiologia PBS de la 25% în anii 1998-1999 şi la 59% între 2000-2002 (13). În studiul prezentat proporţia cazurilor de PBS cu bacterii Gram-pozitive a fost doar 33,33%. În grupul studiat cazurile de PBS cu bacterii Gram-pozitive au prezentat valori mai reduse ale scorurilor Child-Pugh şi MELD şi concentraţii superioare ale proteinelor în lichidul de ascită, comparativ cu PBS cu bacterii Gram-negative.

Ghidurile terapeutice actuale recomandă profilaxia pe termen lung prin administrarea zilnică de Norfloxacin la pacienţii care au prezentat un episod de PBS. Însă, profilaxia cu Norfloxacin ar putea contribui la creşterea frecvenţei PBS cu bacterii rezistente la chinolone, existând studii care au raportat dezvoltarea de bacili Gram-negativi rezistenţi la chinolone în flora intestinală a bolnavilor cirotici ce au primit profilaxie pe termen lung cu Norfloxacin (14).

CONCLUZII

Peritonita bacteriană spontană este o complicaţie frecventă şi severă, ce survine în cazurile de ciroză hepatică cu ascită internate în spital.

Paracenteza diagnostică trebuie efectuată în toate cazurile de ciroză hepatică cu ascită şi când apar manifestări clinice sugestive precum durerile abdominale, febra, encefalopatia hepatică, agravarea disfuncţiei renale sau hepatice. În prezenţa a peste 250 PMN /mm^3 în lichidul de ascită se stabileşte diagnosticul PBS (cultura bacteriană pozitivă nu este absolut necesară) şi se iniţiază tratament antibiotic empiric, preferabil cu cefalosporine de generaţia a III-a (Ceftazidim în studiul prezent). În cazurile cu eşec terapeutic la Ceftazidim trebuie avută în vedere schimbarea acestuia cu Imipenem sau Meropenem.

În pofida progreselor diagnostice şi terapeutice recente, PBS încă se asociază cu o mortalitate semnificativă la bolnavii cu ciroză hepatică, în special în cazurile cu scor MELD ridicat.

CONNECTIONS BETWEEN OBESITY AND COLORECTAL CANCER. THE ROLE OF INFLAMMATION MEDIATED BY GHRELIN AXIS IN ADIPOSE TISSUE (Abstract): Obesity and colorectal cancer are two major global health issues. Although they seem to lack a clear connection, epidemiologic analysis found a significant association. This led to further evaluation and identification of molecular pathways that stand at the basis of these findings. One of them is chronic inflammation, a state associated with obesity and colorectal cancer. Adipose tissue from obese individuals suffers a pathogenic switch responsible for higher inflammatory capacity. This modulates the interplay between inflammation and colorectal cancer cells. Through growth factors and cytokines, adipose tissue creates a favorable microenvironment for tumor development. Our focus is on the ghrelin-growth hormone secretagogue receptor axis which promotes inflammation and has mitogenic and antiapoptotic capacity on cancer cells, acting through various mechanisms including via TNF-α which promotes tumor cell proliferation, growth and metastasis and IL-6, a molecule associated with tumor size and stage in colorectal cancer patients. **Keywords:** OBESITY, COLORECTAL CANCER, ADIPOSE TISSUE, INFLAMMATION, GHRELIN AXIS.

According to World Health Organization (WHO), overweight and obesity can be defined as an accumulation of excessive or abnormal fat which may impair an individual's health. More than 1.9 billion people over 18 years old were overweight in 2016 (1). Body mass index (BMI) is the measurement used to appreciate if an individual is overweight (BMI $\geq$ 25 kg/m^2) or obese ($\geq$ 30 kg/m^2). Excessive development of adipose tissue in the abdominal area has led to the concept of abdominal obesity which has a direct link with metabolic syndrome. Therefore, assessing obesity by measuring waist circumference or waist-to-hip ratio, instead of BMI, recognizes the role of abdominal obesity in metabolic syndrome. Besides cardiovascular and metabolic changes, obesity represents a strong connection between cancer and adipose tissue

cells, being associated with a lower prognosis (2, 3). Moreover, according to American Society of Clinical Oncology, obesity seems to overstep smoking as a risk factor for cancer mortality (4).

Obesity and colorectal cancer

Colorectal cancer (CRC) is the third leading neoplasm in United States (US) population with 97,220 new cases of colon cancer being estimated in 2018 (5). Globally, CRC is the second most common neoplasm in women and third in men. Central and Eastern European countries, including Romania, experience the highest mortality rates regardless of gender (6).

Obesity and CRC have a significant epidemiological association. In a meta-analysis conducted on 153,760 Americans, the relative risk for CRC development was 1.4 in obese men and 1.1 in obese women (7). This gender difference has also been found in other studies, as Harriss *et al.* (8) found in a meta-analysis performed on 67,361 colorectal cases, higher risk rates for colon cancer in male individuals. A possible explanation might be the differences in age at the onset of metabolic syndrome, as well as a possible estrogen protective effect due to inhibition of cell proliferation and apoptosis induction. Another reason could be different methods used for obesity assessment. When evaluated by BMI, the risk for colon cancer was increased in both genders and only in men for rectal cancer, while measurement of waist-to-hip ratio or waist circumference led to higher risk for rectal cancer in both men and women (3, 9).

Adipose tissue inflammation and colorectal cancer

Development of adipose tissue starts in utero with continuous changes throughout life. It is localized in two major areas, the subcutaneous (SAT) and visceral adipose tissue (VAT) (10). Adipocytes are the main cells within this tissue, surrounded by stromal vascular tissue. Adipose tissue can be considered a functional organ with highly metabolic activity, secreting cytokines and chemokines, which act through endocrine and paracrine pathways with impact on surrounding or distant cells, promoting inflammation. This role is mainly attributed to white adipose tissue (WAT). Excessive accumulation of WAT in the subcutaneous and visceral area, together with its abnormal functioning, has led to the concept of adiposopathy (11). It represents the interplay between adipocytes and immune system producing numerous active molecules and maintaining a state of chronic inflammation creating a favorable environment for tumor development. This might be the underlying mechanism explaining the epidemiological association between obesity and cancer (12). In a prospective study, the mortality rate in cancer patients with a BMI over 40 was 52% higher in men and 62% in women (13).

VAT seems to possess higher inflammatory capacity when compared to SAT. Firstly, this may be due to greater cell number, vascular and nerve nutrition and an increased amount of free fatty acids (14). Secondly, adipocyte hypertrophy leads to higher grades of inflammation and greater insulin resistance. Finally, expansion of adipose tissue causes oxygen deprivation among adipocytes. This triggers the hypoxia-inducible factor 1-alpha (HIF-1alpha), activation of macrophage infiltration and inflammation. After infiltrating the VAT, macrophages suffer a switch from an anti-inflammatory (M2) to a pro-inflammatory (M1) phenotype, expressing pro-inflammatory cytokines, such as tumor necrosis-α (TNF-α), interleukin-6 (IL-6),

IL-12 or IL-23, oxygen and nitrogen radicals and increased levels of superoxide anions. Moreover, preadipocytes can behave as macrophage-like cells having phagocytosis capacity and microbicidal activity. Consequently, these cells are a reliable source of growth factors and cytokines contributing to the local microenvironment for tumor growth (15). In fact, systemic and local chronic inflammation is a demonstrated risk factor for CRC in patients with inflammatory bowel disease affecting the colon. Epidemiological data shows that in this category, CRC incidence is increasing progressively, attaining 19% after 30 years evolution of disease (16). Increasing evidence shows that high circulatory levels of adipocytokines such as leptin, adiponectin, resistin, ghrelin and inflammatory cytokines provides a higher risk for CRC (17).

Focus on inflammation mediated by ghrelin axis in the adipose tissue

Ghrelin is a small peptide with a role in insulin secretion and gastric functions, stimulates adipogenesis and modulates another pituitary hormone secretion. It exerts its actions through growth hormone secretagogue receptor (GHSR) which is a receptor with two isoforms, GHSR1a and GHSR1b. GHSR1a is the predominant form, being widely distributed throughout the body. Ghrelin mRNA expression increases during fasting periods (18) which leads to ghrelin release in systemic circulation. This secretion seems to be stimulated by insulin-induced hypoglycemia, supporting the role of a mechanism regulated by plasma glucose levels (19). In obese individuals, plasma ghrelin levels seem to be lower compared with lean individuals (20). This counteracts ghrelin's anti-inflammatory effect and alters adipose tissue macrophages which express GHSR. Activation of GHRS reduces secretion of monocyte chemotactic protein-1 through aNFkB mediated mechanism necessary for monocyte activation. On the other side, ablation of GHSR promotes a macrophage shift from an M1 pro-inflammatory to an anti-inflammatory M2 phenotype in abdominal WAT suggesting that ghrelin's action on immune cells establishes a link between metabolic pathways and inflammation. These findings may be the bridge mechanism between ghrelin, obesity and inflammation with subsequent impact over malignancy.

Ghrelin seems to carry an anti- or a proapoptotic role in different cancer cells, which might be the explanation for discrepancies among study results. However, in a recent study (21), high circulating levels of ghrelin were found in patients with colon cancer in comparison with healthy subjects, being also correlated with tumor size and lower differentiation. Others have found high levels during early colon cancer stage and low levels in the late stage. High levels may be attributed to a compensatory response due to cancer weight loss and protection against cancer-induced inflammation. Administration of intraperitoneal ghrelin reduced significantly the multiplicity of colon adenocarcinomas in an AOM/DSS treatment induced carcinogenesis murine model. Moreover, it reduced the mRNA expression of pro-inflammatory cytokines within proximal colon with a decreased infiltration of neutrophils and F4/80-positive macrophages in the distal colon. Deletion ghrelin gene in mice did not decreased colon tumor formation, but larger tumors were found in $Ghrl^{-/-}$ when compared to wild type mice (22). These findings might suggest that physiological ghrelin secretion might not play the role of carcinogenesis suppressor.

Another mechanism by which ghrelin axis orchestrates carcinogenesis is through pro-inflammatory molecules. Adipocytes are a major source of TNF-α. Chronic high TNF-α expression in colorectal tissue supports tumor cell proliferation, invasion and metastasis. Subsequently, TNF-α activates Wnt, which is a procarcinogenic pathway, controlling cell proliferation, differentiation and apoptosis, being an early event in almost 90% of human CRC (23). TNF-αalso activates NF-kb, responsible for gene expression, which in turn are promoting cell proliferation, apoptosis, metastasis and angiogenesis, therefore enhancing tumor development (24). Moreover, tumor cells with TNF-α expression may escape an individual's immunological defending mechanism by inducing apoptosis in immune cells. Circulating levels of TNF-α in CRC patients can be used to appreciate the clinical outcome, with poorer prognosis when higher levels are achieved (25). Murine models of deficient TNF-α seem to be protected from chemically-induced colon cancer, with similar models for interleukin 2, 6 or 8. IL-6 binds on a soluble receptor (sIL-6R) allowing intracellular signaling mediated through glycoprotein 30 (gp30) and activation of Janus kinases (JAKs) and activator transcription 3 (STAT3) increasing the activation of several target genes. These genes have a role in tumor cell survival, proliferation, angiogenesis, apoptosis, cell adhesion, metastasis and inflammation, high serum and tumoral levels of IL-6 being found in CRC patients. It was also associated with stage, size, metastasis or survival in this category of people (26).

CONCLUSIONS

In summary, we can assert that obesity-associated inflammation represents a favorable microenvironment for tumor development. Ghrelin axis acting by protection against cancer-induced inflammation has a significant impact at molecular level in reducing proliferation and survival of neoplastic colorectal cells. This highlights the key role for ghrelin and inflammatory molecules in possible therapeutic options in obese patients with colorectal cancer.

CAPSULE ENDOSCOPY ROLE IN SMALL BOWEL TUMORS DIAGNOSIS (Abstract): Since the introduction of capsule endoscopy (CE), several studies suggested a higher frequency of small bowel tumors (SBTs) than previously reported. **Material and method**: We evaluated the prevalence, presentation and diagnostic work-up of SBTs în patients undergoing CE în a single referral center. During 2003 - 2009, 102 patients underwent CE. For each patient with suspected SBT at CE, with subsequent histological confirmation, we registered clinical and biological features, imaging methods performed and management. **Results**: SBTs were detected în 4.9% of patients undergoing CE. The main indication for CE was obscure gastrointestinal bleeding. All patients had undergone, before CE, at least one procedure evaluating the small bowel. All patients had iron-deficiency anemia, some presented also other gastrointestinal symptoms. The main SBT type was gastrointestinal stromal tumor. Three patients underwent single-balloon enteroscopy; surgery was performed în all patients. No retention of capsule occurred. CE could be used as first choice as diagnostic tool when SBTs are suspected. **Key words**: SMALL BOWEL TUMORS, CAPSULE ENDOSCOPY, ENTEROSCOPY

Tumorile de intestin subţire reprezintă aproximativ 3-6% din toate tumorile tubului digestiv (1); majoritatea sunt maligne, reprezentând însă doar 1,1-2,4% din tumorile maligne gastrointestinale (2). Diagnosticul tumorilor de intestin subţire rămâne dificil datorită rarităţii lor, tabloului clinic variabil şi nespecific cu care acestea se prezintă, precum şi metodelor inadecvate de investigare a intestinului subţire. Un progres incontestabil în diagnosticul tumorilor de intestin subţire îl aduce videocapsula, tehnică endoscopică revoluţionară prin acurateţe şi siguranţă. Există studii ce susţin că utilizarea acesteia în practică a crescut considerabil rata de diagnostic a tumorilor de intestin subţire, până la 2-9 % (3-7). Folosirea acesteia în cadrul unui algoritm judicios de investigare a intestinului subţire poate asigura diagnosticul şi totodată îmbunătăţi prognosticului pacienţilor cu tumori de intestin subţire.

Studiul de faţă îşi propune să prezinte cazurile de tumori de intestin subţire depistate cu ajutorul videocapsulei pe baza experienţei unui singur centru, analizând frecvenţa acestora, tipul histologic, modalitatea de prezentare clinică, demersul diagnostic complet, tratamentul şi prognosticul.

MATERIAL ŞI METODĂ

Am analizat cazurile de tumori de intestin subţire depistate cu ajutorul videocapsulei endoscopice la pacienţii investigaţi prin această metodă, pentru diverse indicaţii, în Institutul de Gastroenterologie şi Hepatologie Iaşi în perioada 2003-2009.

Au fost analizate modalitatea de prezentare clinică a acestor pacienţi, indicaţia pe baza cărora a fost efectuată investigaţia cu

videocapsula, rezultatele acesteia, investigaţiile efectuate anterior videocapsulei şi ulterior acesteia, localizarea şi tipul histologic al tumorii, conduita terapeutică şi evoluţia pacienţilor.

REZULTATE

Caracteristici generale. Dintre cele 102 investigaţii efectuate cu videocapsula endoscopică de intestin subţire în perioada 2003--2009 în Institutul de Gastroenterologie şi Hepatologie Iaşi, în cinci cazuri au fost depistate tumori de intestin subţire, ulterior confirmate histologic, reprezentând 4,9% din cazuri. Din cei cinci pacienţi, trei au fost de sex masculin, doi de sex feminin, vârsta fiind cuprinsă între 39 şi 72 de ani.

Indicaţia videocapsulei de intestin subţire. Indicaţia de efectuare a videocapsulei de intestin subţire a constituit-o la toţi cei cinci pacienţi hemoragia digestivă de cauză obscură, la trei pacienţi manifestându-se prin testul hemoragiilor oculte pozitiv şi anemie feriprivă, iar la doi pacienţi prin hemoragie digestivă manifestă; în toate cazurile etiologia a rămas neprecizată după investigaţiile endoscopice de primă linie (endoscopie digestivă superioară şi colonoscopie).

Tablou clinic asociat. Pacienţii investigaţi pentru hemoragie digestivă manifestă (melenă) de cauză obscură nu au prezentat simptome digestive asociate, ci doar simptome caracteristice sindromului anemic (astenie, vertij). În cazul pacienţilor a căror indicaţie de videocapsulă a constituit-o hemoragia digestivă ocultă, s-au înregistrat ca simptome asociate scăderea ponderală la doi pacienţi, sindrom dispeptic manifestat prin greaţă, disconfort abdominal postprandial la un pacient, precum şi tablou sugestiv de subocluzie (dureri abdominale intermitente crampiforme, vărsături alimentare, încetinirea tranzitului intestinal) la alt pacient. De altfel, motivul consultului gastroenterologic l-a constituit la această din urmă categorie de pacienţi simptomatologia digestivă, probele biologice de rutină evidenţiind sindrom anemic feripriv, cu testul hemoragiilor oculte pozitiv.

Investigaţii efectuate anterior şi ulterior videocapsulei. Toate investigaţiile cu videocapsula au fost realizate urmărind algoritmul de investigare al hemoragiei digestive oculte/obscure, toţi cei cinci pacienţii fiind investigaţi anterior videocapsulei prin endoscopie digestivă superioară şi inferioară (ambele negative), la doi din cei cinci pacienţi efectuându-se şi endoscopie digestivă superioară second-look.

Un pacient care prezenta simptomatologie digestivă manifestă ca sindrom subocluziv a efectuat înainte de videocapsulă tranzit de intestin subţire şi tomografie computerizată abdominală, fără diagnostic.

Un pacient care prezenta melene repetate a efectuat înainte de videocapsulă scintigrafie cu hematii marcate, care a evidenţiat sursă de sângerare la nivelul cadranului abdominal superior stâng.

Doi pacienţi au efectuat după videocapsulă enteroscopie care a identificat leziunea, a descris suplimentar caracteristicile macroscopice şi a stabilit localizarea, în preambulul intervenţiei chirurgicale.

Aspect endoscopic, localizare şi diagnostic histologic. Într-un caz s-a evidenţiat la videocapsulă doar sângerare activă la nivelul jejunului, fără a se identifica o leziune propriu-zisă subjacentă. La acest pacient, laparotomia exploratorie a stabilit diagnosticul de adenocarcinom avansat. La ceilalţi patru pacienţi aspectul a fost de masă (leziune protruzivă). La un pacient au fost evidenţiate două leziuni protruzive ocupând circa un sfert din lumenul intestinal ileal, una cu modificare minimă a culorii mucoasei cu aspect uşor albicios, cealaltă cu mucoasă de aspect aparent normal, ridicând în discuţie şi diferenţierea de un relief format în dinamică; în acest caz diagnosticul final histologic în urma laparoscopiei cu rezecţie de ileon a fost tumoră carcinoidă.

Fig. 1. Masă cu ulceraţie minimă duodenală

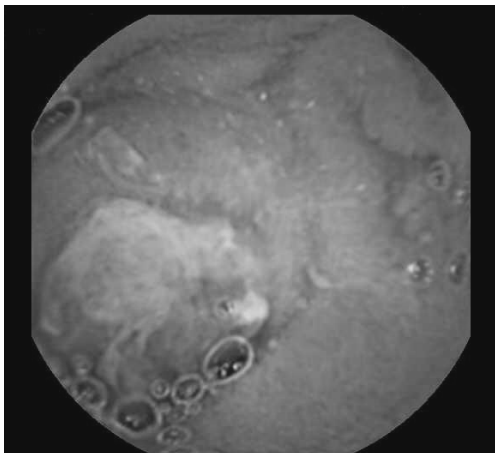

Fig. 2. Leziune ulcerată jejunală

La un pacient, masa protruzivă ocupa aproximativ o treime din lumenul duodenal şi prezenta ulceraţie minimă (fig. 1). Diagnosticul histologic al piesei operatorii a fost de tumoră stromală duodenală. La un pacient, leziunea protruzivă se prezenta pe circa o treime din circumferinţa jejunului, cu aspect modificat al culorii mucoasei (violacee); diagnosticul pe piesa operatorie a fost de tumoră stromală jejunală. La un pacient, masa protruzivă jejunală prezenta aspect ulcerat evident (fig. 2). Diagnosticul histologic pe piesa operatorie a fost de asemenea de tumoră stromală jejunală. La nici unul din aceşti patru pacienţi nu a fost evidenţiată sângerare activă din leziune, dar la cei din urmă doi pacienţi au fost vizibile cheaguri de sânge în lumenul intestinal în vecinătatea leziunii sau în aval de aceasta. Nu au fost evidenţiate stenoze.

Timpul de tranzit intestinal al videocapsulei. Timpul de tranzit intestinal a variat larg, între 2 ore şi 10 minute şi peste 8 ore.

Conduita terapeutică. Toţi pacienţii au fost referiţi serviciului de chirurgie, trei pacienţi imediat după efectuarea videocapsulei, doi pacienţi după ce a fost efectuată şi enteroscopie ulterior videocapsulei.

Un pacient a fost diagnosticat intraoperator cu adenocarcinom avansat şi nu a beneficiat de sancţiune curativă; unui pacient cu descriere intraoperatorie de stenoze ileale multiple i s-a efectuat enterectomie segmentară, efectuând apoi în urma diagnosticului histopatologic de tumoră carcinoidă chimioterapie specifică. Trei pacienţi au beneficiat de rezecţii segmentare curative pentru tumori stromale.

Evoluţie. Un pacient diagnosticat cu adenocarcinom avansat a evoluat rapid nefavorabil.

Un pacient cu tumoră carcinoidă rezecată şi chimiotratată a prezentat evoluţie favorabilă cu lipsa recidivei la patru ani după intervenţie. Trei pacienţi cu tumoră stromală jejunală benignă au evoluat favorabil postoperator.

DISCUŢII

Frecvenţa tumorilor de intestin subţire depistate a fost de 4,9 % din totalitatea investigaţiilor efectuate cu videocapsula în perioada 2003-2009 în Institutul de Gastroenterologie şi Hepatologie Iaşi, cei cinci pacienţi diagnosticaţi aparţinând unei serii de 102 pacienţi investigaţi pentru diferite indicaţii. Procentul este asemănător altor serii de dimensiuni similare comunicate până acum, respectând constatarea unui studiu multicentric european din 2008 privind corelaţia inversă a frecvenţei tumorilor de intestin subţire detectate cu numărul total

de investigaţii efectuate (8), explicaţia constând probabil în stricteţea criteriilor de investigare cu videocapsula aplicate.

În centrul nostru, videocapsula a fost administrată respectând riguros indicaţiile stabilite consensual, toate explorările fiind efectuate pentru hemoragie digestivă de cauză neprecizată, manifestă sau ocultă. La doi pacienţi, hemoragia digestivă manifestă de cauză rămasă neprecizată după endoscopie digestivă superioară şi colonoscopie a motivat administrarea videocapsulei, iar la ceilalţi trei pacienţi indicaţia a constat în depistarea biologică a anemiei feriprive cu testul hemoragiilor oculte pozitiv. Au fost evidenţiate tumori ce s-au dovedit maligne la doi pacienţi (adenocarcinom şi respectiv tumoră carcinoidă), un caz în stadiu avansat ce nu mai beneficiat de tratament curativ. Ordinea investigaţiilor a depins de simptomatologia dominantă – de exemplu s-a efectuat tomografie computerizată abdominală la pacientul cu sindrom subocluziv înaintea videocapsulei. Videocapsula a fost efectuată fie cu indicaţie *negativă* - prin lipsa de elucidare a diagnosticului după alte investigaţii, fie cu indicaţie *pozitivă* - impusă de o investigaţie anterioară cu rezultat patologic (scintigrafie cu hematii marcate).

Enteroscopia a fost efectuată în două cazuri după videocapsulă şi înaintea intervenţiei chirurgicale, aducând informaţii suplimentare privind aspectul şi localizarea tumorii. Sensibilitatea superioară a videocapsulei în detectarea leziunilor intestinului subţire faţă de alte metode a fost evidenţiată de multiple studii (9,10,11,12), studii recente sugerând eficienţa comparabilă a CE cu enteroscopia (13,14). Într-adevăr, în seria studiată, pacienţii care au efectuat enteroscopie au beneficiat de o descriere macroscopică suplimentară a leziunii, în preambulul intervenţiei chirurgicale. Timpul de tranzit intestinal a variat larg între 2 ore şi 10 minute şi peste 8 ore. Momentul depistării leziunii s-a corelat cu timpul de tranzit intestinal în sensul unui timp total de tranzit mai scurt în cazul leziunilor descrise proximal pe traiectul intestinului subţire şi al unui timp de tranzit prelungit (chiar peste durata de funcţionare a capsulei) în cazul leziunilor descrise distal, în a doua jumătate a intestinului subţire. Aceasta ar putea ridica ipoteza influenţării timpului de tranzit de către tumoră (prin stază suprajacentă sau motilitate afectată în segmentul din amonte). Desigur că observaţia necesită validare, prin studierea unui număr mai mare de cazuri.

Ca localizare a fiecărei tumori în raport cu tipul histologic, distribuţia a respectat tendinţele descrise în literatură (15) : tumora carcinoidă a avut sediu ileal, iar tumorile stromale au fost localizate jejunal. Am constatat că nu există o corelaţie între impactul vizual imediat al leziunilor şi severitatea diagnosticului. De altfel putem susţine că obiectivul capsulei nu trebuie sa fie diagnosticul cert, ci evidenţierea de indicii care impun continuarea demersului diagnostic, fie cu alte metode dedicate intestinului subţire (enteroscopie), fie laparotomie.

Nu au fost înregistrate complicaţii la nici unul dintre cazuri, videocapsula dovedindu-se o tehnică atât neinvazivă, cât şi sigură.

Toţi pacienţii au fost referiţi chirurgiei, trei pe baza rezultatului videocapsulei, doi după efectuarea în completare a enteroscopiei care a adus un plus de informaţii privind aspectul şi topografia leziunilor. Videocapsula a dictat singură indicaţia chirurgicală în cazurile în care există tablou clinic invalidant şi în cazul evidenţierii de sângerare activă fără identificare de leziune, aşadar în situaţiile când probabilitatea de a se recurge într-un final la sancţiune chirurgicală era destul de ridicată.

CONCLUZII

Procentul de tumori de intestin subţire evidenţiate la videocapsulă este mic, în contextul respectării standardului investigaţio-

nal al hemoragiei digestive obscure (oculte sau manifeste). Ar fi utile studii care să estimeze frecvenţa tumorilor de intestin subţire depistate de videocapsulă aplicată pentru alte indicaţii, pentru a stabili dacă, pentru a păstra cost-eficienţa, algoritmul trebuie păstrat sau, dimpotrivă, lărgirea indicaţiilor asigură creşterea randamentului.

Videocapsula endoscopică nu oferă diagnosticul final al tumorilor de intestin subţire, dar semnalează leziuni a căror semnificaţie ar putea fi anticipată prin analiza minuţioasă a caracteristicilor macroscopice. Ar fi necesară stabilirea în acest scop unor criterii vizuale cit mai fiabile şi de acurateţe crescută.

Videocapsula poate motiva decizia chirurgicală fie independent, fie completată de enteroscopie, în funcţie de suspiciunea clinică.

După cum am subliniat şi într-o analiză anterioară, videocapsula poate fi utilizată ca primă alegere în cazul suspiciunii de tumoră de intestin subţire, fiind urmată, dacă este necesar, de enteroscopie (cu balonaş unic sau dublu), pentru precizare histologică şi eventual tratament endoscopic (16,17).

THE IMPACT OF FAMILIAL HYPERCHOLESTEROLEMIA ON CARDIOVASCULAR DISEASE (Abstract): Familial hypercholesterolemia is one of the most common inherited diseases, that leads to an important cardiovascular morbidity and mortality, especially in developed countries. It is characterized by early coronary artery disease associated with cholesterol deposits that lead in time to atherosclerotic plaques, because of high levels of circulating cholesterol for a long period of time. Romania is in the group of countries at high risk for cardiovascular disease, being recommended that all internal medicine doctors and cardiologists use the SCORE Risk Chart, to calculate the cardiovascular risk for the next 10 years. The causes of hypercholesterolemia are multiple. On the one hand, the exogenous intake of dietary principles with high cholesterol content is incriminated, and on the other hand is the involvement of the genetic factor. Regarding the treatment in familial hypercholesterolemia, the most recent guidelines state that statins are the mainstay of treatment, but in addition we can also use new drugs like PCSK9 inhibitors, in combination with lifestyle changes. Through this article, we want to draw attention once again to the need for hypercholesterolemia treatment, in line with the latest recommendations of the guidelines. **Keywords**: FAMILIAL HYPERCHOLESTEROLEMIA, SCORE RISK CHART, CARDIOVASCULAR DISEASE.

Familial hypercholesterolemia is one of the most common inherited diseases, that leads to an important cardiovascular morbidity and mortality, especially in developed countries. It is characterized by early coronary artery disease associated with cholesterol deposits that lead in time to atherosclerotic plaques, because of high levels of circulating cholesterol for a long period of time. Aging and modern lifestyles have been increasingly associated with high levels of cholesterol in people all around the world, this being one of the most important cardiovascular risk factors (1). Regarding the mentioned risk, researchers described in the last dyslipidemia guideline that was published in 2016the importance of screening in all men over 40 years and in all women over 50 years or post menopause. By screening, they refer to the evaluation of all lipid fractions (total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides) (2).

Moreover, given the fact that Romania is in the group of countries at high risk for

cardiovascular disease, it is recommended that all internal medicine doctors and cardiologists use the SCORE Risk Chart, to calculate the cardiovascular risk for the next 10 years. Within the SCORE Risk Chart, it is taken into consideration the value of cholesterol, blood pressure, the smoker / non-smoking status, age and the patient gender. The main factor in calculating total cardiovascular risk through the SCORE Risk Chart is total cholesterol (3).

The causes of hypercholesterolemia are multiple. The exogenous intake of dietary principles with high cholesterol content and/or the involvement of the genetic factor are incriminated. Thus, we can say that hypercholesterolemia can have monogenic or multifactorial determinism. The most common monogenic form (1/200 individuals) is familial hypercholesterolemia (4, 5). The disease is transmitted predominantly autosomal dominant (new mutations are extremely rare) and is caused by mutations in LDLR genes (60-80% of cases), APOB (1-5% of cases) and PCSK9 (0-3% of cases), in 20-40% of cases the defect remaining unknown.

Differential diagnosis includes hypercholesterolemia secondary to obesity, diabetes, hypothyroidism, drugs or kidney disease, where the distribution of cases in the family is non-mandala. Also included in the differential diagnosis are autosomal recessive hypercholesterolemia (LDLRAP1 gene mutations), combined familial hyperlipidemia (associated with increased value of LDL-C and triglycerides, produced by mutations in the LPL gene) and polygenic hypercholesterolemia (determined by various genetic polymorphisms and environment side effects).Genetic testing is indicated in people with a family history of hypercholesterolemia and consists of complete sequencing (including 5', 3' regions and introns) of the LDLR, APOB and PCSK9 genes (in this order). Next Generation Sequencing can check the sequence of the three genes at the same time. In negative cases, it is recommended to study polymorphisms that are associated with hypercholesterolemia (6).

In heterozygous patients that are not receiving treatment, cholesterol levels typically range between 250 and 300 mg/dL and cardiovascular events develop in men by 30–50 years and in women by 40-60 years. On the other hand, in homozygous patients, the cholesterol levels are much higher (500-1000 mg/dL), and important atherosclerotic events start from early childhood. If left untreated, homozygous patients generally die before the age of 30 years due to accelerated severe atherosclerotic cardiovascular events (1).

The latest studies show that in Europe are approximately 4.5 million people that are affected by familial hypercholesterolemia, of whom 20-25% are children and adolescents. Of those, less than 10% are diagnosed. For a better quantification of dyslipidemia, it is necessary to dose each lipid fraction: HDL-cholesterol, which has the role of cardiovascular protection, respectively LDL-cholesterol, the main factor determining the atherosclerosis process, regardless of age (7). According to the Safe heart cohort data, only 68.2% of patients with familial hypercholesterolemia younger than 18 years old are on statins, and only 41.5% of patients had LDL-C < 3.4 mmol/L(8).

Patients with familial hypercholesterolemia may show clinical manifestations, like corneal arcus, xanthelasmas and xanthomas, but they should be looked after with attention, this leading to an earlier diagnosis and

treatment. Worldwide, familial hypercholesterolemia is underdiagnosed and undertreated, generally being detected late in adults, in part because existing diagnostic criteria are complex and not widely used outside of specialty lipid clinics (9, 10).

There are described 3 different criteria for familial hypercholesterolemia diagnosis. First, there is Simon Broome criteria that includes familial history, clinical signs, cholesterol values and genetic testing (tab. I). The advantage of this criteria is that it is very easy to remember and its applicability in a day-to-day clinic is easy and effective. The disadvantage would be that Simon-Broome criteria fails to differentiate between classical familial hypercholesterolemia due to LDLR mutations and the other genetic origins of familial hypercholesterolemia such as ApoB-100 and PCSK9 (11).

TABLE I

Simon Broome familial hypercholesterolemia register diagnostic criteria for familial hypercholesterolemia (adapted after Singh, 2015)

Criteria	Description
1	Total cholesterol concentration above 7.5 mmol/L (290 mg/dL) in adults or a total cholesterol concentration above 6.7 mmol/L (260 mg/dL) in children aged less than 16 years, or low-density lipoprotein (LDL) cholesterol concentration above 4.9 mmol/L (190 mg/dL) in adults or above 4.0 mmol/L (155 mg/dL) in children
2	Tendinous xanthoma in the patient or a first-degree relative
3	DNA-based evidence of mutation in the LDLR, Apo B-100, or PCSK9 mutation
4	Family history of myocardial infarction before age 50 years in a second-degree relative or before age 60 years in a first-degree relative
5	Family history of raised total cholesterol concentration above 7.5 mmol/L (290 mg/dL) in a first- or second-degree relative or greater than 6.7 mmol/L (260 mg/dL) in child or sibling aged younger than 16 years

"Definite" FH diagnosis requires either criteria 1 and 2 or criteria 3.
"Probable" FH diagnosis requires either criteria 1 and 4 or criteria 1 and 5.

The second criteria is Dutch Lipid Clinic Network diagnostic criteria. They are similar to the Simon Broome register criteria but require that at least one clinical criterion be met besides molecular DNA diagnosis for FH to be diagnosed (tab. II). The most important advantage of this criteria is that it addresses the molecular defect that leads to FH and this in turn will help to provide the diagnosed FH patient with a better therapeutic strategy/treatment. The disadvantages would be the lack of versatility and the fact that is very expensive (12).

The third is US MedPed program diagnostic criteria, that have total cholesterol cutoffs derived from mathematical models constructed using published cholesterol levels for familial hypercholesterolemia individuals in the USA and Japan. The cutoffs consider degree of relatedness (individuals with a relative with familial hypercholesterolemia have a higher probability of having the disease) and age (as cholesterol levels increase with age) (11, 12) (tab. III).

Reducing cholesterol levels is essential and can be achieved by lifestyle changes and by using pharmacological agents such as statins or newer therapy such as inhibitors of proprotein convertase subtilisin-kexin type 9 (13). In addition, many studies

suggest that for a better lowering of the LDL-cholesterol, a decrease in triglyceride and lipoprotein (a) would reduce the risk of ischemic cardiopathy (14).

TABLE II

Dutch Lipid Clinic Network diagnostic criteria for familial hypercholesterolemia (adapted after Singh, 2015)

Criteria	Points
Family history	
First-degree relative with known premature (men <55 years; women <60 years) coronary and vascular disease, or first-degree relative with known LDL-C above the 95th percentile	1
First-degree relative with tendinous xanthomata and/or arcus corneal is, or children aged less than 18 years with LDL-C above the 95th percentile	2
Clinical history	
Patient with premature (men <55 years; women <60 years) cerebral or peripheral vascular disease	1
Patient with premature (men <55 years; women <60 years) coronary artery disease	2
Physical exam	
Arcus corneal is prior to age 45 years	4
Tendinous xanthoma	6
Cholesterol levels mmol/L(mg/dL)	
LDL-C 4.0–4.9 (155–193)	1
LDL-C 5.0–6.4 (193–251)	3
LDL-C 6.5–8.4 (251–329)	5
LDL-C ≥8.5 (329)	8
DNA tests	
Functional mutation in the LDLR gene	8

"Definite" FH diagnosis requires more than 8 points.
"Probable" FH diagnosis requires 6–8 points.
"Possible" FH diagnosis requires 3–5 points.

TABLE III

US MedPed program diagnostic criteria for probable heterozygous familial hypercholesterolemia (adapted after Al-Rasadi, 2014)

Age (years)	Total cholesterol cut points mmol/L(mg/dL)			
	First-degree relative with FH	Second-degree relative with FH	Third-degree relative with FH	General population
<20	5.7 (220)	5.9 (230)	6.2 (240)	7 (270)
20–39	6.2 (240)	6.5 (250)	6.7 (260)	7.5 (290)
30–39	7 (270)	7.2 (280)	7.5 (290)	8.8 (340)
≥40	7.5 (290)	7.8 (300)	8 (310)	9.3 (360)

Regarding the treatment in familial hypercholesterolemia, the most recent guidelines state that statins are the mainstay of treatment, in combination with lifestyle changes. In a cohort study realized on 2,146 patients diagnosed with familial hypercholesterolemia but without coronary heart disease, after a follow-up of 8.5 years, the treatment with statins reduced the risk for coronary heart disease by 76%.

According to the guidelines, if the patient does not reach the LDL-cholesterol targets with the highest recommended or tolerable dose of statin, it should be considered the combination with ezetimibe. If the patients still do not reach the LDL-cholesterol targets after ezetimibe and statins, bile acid sequestrants can be considered (15).

Monoclonal antibodies against proprotein convertase subtilisin-kexin type 9 (PCSK9) are proteases that are synthesized in the liver and small intestine. PCSK9 is secreted from liver cells, binds to the LDL receptor and is subsequently internalized together with the LDL receptor and targets the receptor for lysosomal degradation. Therefore, the inhibition of PCSK9 determines an increased expression of LDL receptors on hepatocytes and decreased LDL-C levels in the circulation. This leads to the fact that patients with the loss of function mutations in the PCSK9 gene have very reduce LDL-C level, whereas the gain of function mutations cause familial hypercholesterolemia. Commercially available are two monoclonal antibodies that inhibit PCSK9, alirocumab and evolocumab (15).

CONCLUSIONS

In our study we considered the importance of the implication of non-modifiable risk factors (age, gender, genetic factors) in the development of cardiovascular disease, being required a more stringent control of the modifiable factors (blood pressure, blood glucose, cholesterol, stress). Through this article, we want to draw attention once again to the need for hypercholesterolemia treatment, in line with the latest recommendations of the guidelines.

NEWS

A NEW HOPE FOR AN OLD HEART? CAN INTERFERON-FREE THERAPY ALSO REVERSE THE HCV-INDUCED CARDIOMYOPATHY IN PATIENTS WITH END-STAGE HEART FAILURE?

Several studies have previously confirmed an association between hepatitis C virus (HCV) infection and cardiomyopathy, but none could really establish a pathogenic relationship. These issues have arisen because the classic, interferon-based therapy for HCV infection has severe cardiac side-effects, thus limiting its use in patients with advanced heart failure. The aim of this prospective large-scale study was to assess the benefits of using interferon free regimens in HCV-infected patients with non-valvular, non-ischemic cardiomyopathy, the standard treatment (consisting of ombitasvir, paritaprevir, dasubavir and paritaprevir) being well-tolerated, free of cardiac side-effects. The authors were encouraged to conduct a large study because they observed that this treatment was very effective in a patient with rapidly progressive heart failure (NYHA III/IV class), who was already listed for heart transplantation. In order to have an acceptable hepatic functional status prior to the transplant, the patient received the interferon-free regimen and, surprisingly, after her complete HCV clearance, her cardiac function improved significantly to NYHA II class, heart transplant being no longer considered. The conclusion was that HCV was etiopathogenetically involved in myocardial dysfunction for at least two reasons: the interferon-free therapy does not eliminate any other cardiotropic virus (e.g. Coxsackie B3), nor does it have „per se" any antifibrotic or cardiac antiremodelation action. These promising findings need to be further confirmed on larger patient cohorts in this ongoing study. Poller W, Haghikia A, Kasner M *et al*. Cardiovascular Involvement in Chronic Hepatitis C Virus Infections - Insight from Novel Antiviral Therapies. *J Clin Transl Hepatol* 2018; 6(2): 161-167.

INDICATIONS AND CONTRAINDICATIONS IN TRAUMATIC PATHOLOGY IN PATIENTS WITH DEMENTIA

INDICATIONS AND CONTRAINDICATIONS IN TRAUMATIC PATHOLOGY IN PATIENTS WITH DEMENTIA (Abstract): The incidence of patients with dementia has increased significantly in the last decades, with the increase in life expectancy and longevity; it is a condition age-specific and doubles with every 5 years of increase in age and it is expected to reach 65,7 million in 2030 and 115.4 million by 2050. In cases of dementia, it is contraindicated any stressful emotional or physical situation that could precipitate symptoms. In the case of trauma, there is a complex process that disturbs the homeostasis of the whole organism. It is known that the elderly has an increased risk of delirium (which is basically a separate transient illness, not a worsening of dementia, so it is reversible) during the postoperative period, and the more patients with dementia who can develop both delirium and postoperative cognitive dysfunction. An important step in general anesthesia is the anesthetic preconditioning in which the brain is stimulated by small lesions that do not produce histological changes but are sufficient to produce a biomolecular stress that will initiate protection against further severe aggressions. In conclusion, patients with dementia have a high mortality rate and therefore require careful supervision and immediate care when first suspicions arise. Delirium should be treated as a deadly emergency. They also need palliative therapies for both pain and support to provide a more familiar environment to reduce depression and anxiety. **Keywords:** TRAUMATIC PATHOLOGY DEMENTIA, ELDERLY.

The incidence of patients with dementia has increased significantly in the last decades, with the increase in life expectancy and longevity (1); it is a condition age-specific and doubles with every 5 years of increase in age (2) and it is expected to reach 65.7 million in 2030 and 115.4 million by 2050 (3, 4).

Dementia is a neurological disorder specific to the elderly and is generally recognized by a combination of symptoms such as personality disorders, memory loss and intellectual regression, transformations that have a major impact on everyday life, personal independence and inter-human relationships (5, 6, 7). Therefore, the scien-

tific world has shown interest into dementia, and over the last two decades many details have been revealed about dementia neurobiology in terms of molecular mechanism, bringing attention to unprecedented insight into this incurable disease (1).

As we age, the brain changes its' structure and chemistry (8, 9, 10). In dementia was seen that cells lose the ability to communicate with each other and eventually die (10).

If dementia occurs as a reaction to certain medications or because of a vitamin deficiency, treatment can considerably improve the patient's condition, or even cure the condition, but unfortunately, the most common forms of dementia are degenerative, especially Alzheimer's disease. But there are other types of dementia, such as vascular dementia, dementia with Lewy bodies, frontotemporal dementia, mixed dementia, Huntington's disease, Creutzfeldt-Jacob disease and pugilistic dementia (a variant of chronic traumatic encephalopathy), that differentiate both etiologically and symptomatically.

However, some of these diseases (Alzheimer's dementia, frontotemporal dementia, dementia with Lewy bodies) share a common feature: **excessive buildup of proteins in the brain** which become toxic and harm both the brain and nerve cells (10). So, the main symptoms are memory loss, disability to carry out daily tasks, personality and behavior problems such as loss of interest in daily activity, loss of confidence, sleep disorders. As the disease progresses, the brain's ability to adapt to changes and absorb certain drugs is also reduced.

In cases of dementia, it is contraindicated any stressful emotional or physical situation that could precipitate symptoms. In the case of trauma, there is a complex process that disturbs the homeostasis of the whole organism.

Generally, stress determine a hyperactivity of the hypothalamic pituitary adrenal (HPA) cortical axis with an excessive production of glucocorticoid stress hormone (cortisol). The three most important regulators of the HPA axis are the *amygdala* (has excitatory influence – recognize threat and coordinate the fear response), the *hippocampus* (inhibitory – explore the environment under safe conditions) and *prefrontal cortex* (inhibitory). Some studies showed that chronic elevated levels of cortisol lead to brain atrophy (11). Similarly, in dementia are observed the atrophy in hippocampus, inferior parietal and posterior cingulate cortex (specific for Alzheimer's disease) and thalamus and striatum (specific for frontotemporal dementia) which indicate the progression of these pathologies (12). Knowing these specific regions, we can use trial targeted treatments in the future to slow the progression of atrophy (12). We therefore deduce that it is important to limit stress factors on the patient with dementia because it decompensates the patient very quickly, accentuates atrophy, causes the appearance of delirium, which if not properly treated or unnoticed in time can lead to an exitus.

It is known that the elderly has an increased risk of delirium (which is basically a separate transient illness, not a worsening of dementia, so it is reversible (8)) during the postoperative period, and the more patients with dementia who can develop both delirium and postoperative cognitive dysfunction. It is estimated that 90% of patients with dementia develop delirium after important surgeries like hip surgery or radial head fractures Mason III (although

bipolar polyethylene prosthesis offers an easier implantation) (13).

So, it is best to be aware of the patient's condition in the trauma and orthopedics unit of one acute hospital (14). This will guide the choice of anesthesia (general or regional) and drugs' administration because some anesthetic drugs might impair the memory and cognitive function and also allow to monitor and treat as aggressively as possible to limit poor cognitive and functional impairment (15, 16).

Anesthetic medication has multiple effects:

- isoflurane induces diffuse neuroapoptosis;
- thiopental, midazolam and protoxide amplify this effect;
- sevoflurane inhibits neutrophil apoptosis;
- some neuromuscular blockers and some local anesthetics induce apoptosis;
- propofol delays synaptic axonal development (17).

An important step in general anesthesia is the **anesthetic preconditioning** in which the brain is stimulated by small lesions that do not produce histological changes but are sufficient to produce a biomolecular stress that will initiate protection against further severe aggressions.

Generally, surgical procedures lead to inflammation and immunological responses which can affect the brain due to the fact that blood flow to the brain can be impaired because of changing fluid levels or blood loss. Moreover, some surgical procedures might increase the risks of small strokes (15).

Patients with dementia also present an increased risk of other complications that are difficult to diagnose in initial stage including pneumonia, septicemia, stroke, pressure ulcers, acute renal failure requiring dialysis, urinary tract infection, lung failure requiring intubation, falls and incontinence (2, 5, 12, 18). All of these are also associated with an increase in the number of hospitalization days, higher costs of medical care and a high mortality rate (2, 5, 16).

It is estimated that mortality (5, 19, 20, 21) in first 7 days after surgery reach 14%, compared to non-dementia patients (6%) (5). Dementia it is also associated with high rate of morbidity and mortality which reach to 92% in two years, compared with 7% at those without dementia (2, 10).

DISCUSSION

As we have said so far, patients with dementia have an increased risk of severe complications. Therefore, in these patients it is recommended first, conservative treatment instead of the surgical procedure is recommended. Unfortunately, in most cases surgery is unavoidable, and it is crucial to prevent as much as possible any complications.

Demented patients do not require a specific medication before anesthesia, but sometimes it is necessary to use anxiolytics or short-acting benzodiazepines to prevent or reduce some symptoms like anxiety, irritability and agitation, specific to dementia (2).

The surgical team should be knowledgeable about the patients' illness, the medication they are taking, the associated comorbidities and how any previous anesthetics have affected them because elderly, but especially demented patients have an increased sensitivity to the drugs of anesthesia. So, the anesthetist will titrate and administer smaller doses to also prevent anesthetic-induced circulatory depression (2). In

some cases, regional anesthesia is a better choice, although there are not specific studies to prove a significant advantage of this anesthesia due to the fact that most studies do not include this category of patients.

On the other hand, it is very important to treat pain properly because demented patients are less likely to report sensations of pain, but pain may precipitate the condition of the patient with dementia and cause depression and delirium (2, 8). At the same time, delirium might suggest an infection or pain (8).

Finally, patients with dementia should completely eliminate specifying factors such as smoking and alcohol (cause permanent brain damage) which can precipitate the symptoms, although it is well known that small quantities of wine have positive influence in bones consolidation (22).

CONCLUSIONS

Patients with dementia have a high mortality rate and therefore require careful supervision and immediate care when first suspicions arise. Delirium should be treated as a deadly emergency. They also need palliative therapies for both pain and support to provide a more familiar environment to reduce depression and anxiety.

CONTRAST ENHANCED ULTRASONOGRAPHY: ADVANTAGES AND CONTRAINDICATIONS

Contrast agents for ultrasonography (US) were first introduced in 1996 and have been used mainly for echocardiography, Doppler US and abdominal US. Contrast-enhanced US (CEUS) has several advantages over the contrast-enhanced computed tomography (CECT) or contrast-enhanced magnetic resonance imaging (CEMR), such as no radiation, no harmful effects to the kidney or thyroid, easy accessibility and comparable comfort during use, but it has not been widely used in abdominal applications. In the case of first-generation US contrast agents, early breakdown of microbubbles limits the contrast effect during continuous scanning. With the development of second-generation US contrast agents in 2001 and the advances of the contrast-specific mode with a low-mechanical index (MI) technique in US machines, a real-time evaluation has become possible, resulting in an increasing interest in US contrast agents and CEUS. A US contrast agent is excreted via the lung after the destruction of the microbubbles; hence, it is not nephrotoxic. Further, it does not contain iodine, thereby not having any effect on the thyroid functions. Although the US contrast agent is very safe, it can be regarded as a foreign material by the immune system; therefore, a hypersensitivity reaction is possible. The incidence of a severe hypersensitivity reaction was reported in about 0.002%. The overall reported incidence of the hypersensitivity reaction was less than that occurring with the use of an iodine contrast agent in CT and was similar to that of the use of a gadolinium chelate contrast agent in MRI. Contraindications of US contrast agents are: a recent acute coronary syndrome, right-to left shunts, severe pulmonary hypertension, uncontrolled systemic hypertension and adult respiratory distress syndrome. Recently, the use of one US contrast agent in echocardiography has been temporarily suspended because of possible severe hypertension, bradycardia, cardiac arrest, and acute myocardial infarction and for another contrast agent in patients with egg allergies. Because the safety of some contrast agents has not been evaluated in pregnant women, in women who are breast-feeding, or in patients who are younger than 18 years of age using them should be avoided in these patients.

HOME CONTROL OF HIGH BLOOD PRESSURE (Abstract): Control of blood pressure is far from satisfactory, reaching ~ 13% in Romania according the SEPHAR study. **Aim**: Assessment of blood pressure control in elderly by blood pressure monitoring at home. **Material and method**: 64 hypertensive patients (36 women and 28 men) with mean age of 76.3 years which blood pressure has been normalized by admitting in hospital were followed for a period of three months, by self-measuring blood pressure at home (twice a week). **Results**: In the first week after hospital discharge the mean systolic pressure was 158± 17.06 and after adjustment of treatment was 136.76± 11.36 mmHg. To the end of the study blood pressure was controlled at a rate of 81.25 %. **Conclusions**: To increase the percentage of therapeutic control of blood pressure at home, small changes in drug dosage are needed. **Key words**: BLOOD PRESSURE CONTROL, ADJUSTING TREATMENT, HOME CONTROLED BLOOD PRESSURE

Controlul valorilor tensionale este departe de a fi satisfăcător, atingând în România ~ 13% după rezultatele studiului SEPHAR dar şi în ţările cele mai dezvoltate doar un procent de maximum 27% dintre pacienţii hipertensivi trataţi sunt controlaţi terapeutic. In practica medicală, tratamentul hipertensiunii arteriale (HTA) este orientat frecvent doar de valorile presiunii arteriale pe care pacientul le prezintă în timpul spitalizării. Din punct de vedere fiziopatologic, există o serie de mecanisme diverse, adesea intricate, implicate în realizarea unor valori presionale crescute la domiciliu, care determină creşterea debitului cardiac sau a rezistenţei vasculare periferice. Consecinţele sunt rezistenţa la tratament, apariţia reacţiilor adverse de tip fatigabilitate, cefalee, tulburări digestive, inapetenţa etc., manifestări ce duc la scăderea complianţei pacientului la tratamentul recomandat.

OBIECTIVE

Aprecierea controlului tensiunii arteriale (TA) la vârstnicii hipertensivi prin monitorizarea clinică a valorilor tensiunii arteriale la domiciliu.

MATERIAL ŞI METODĂ

Lotul de studiu a fost format din 64 pacienţi hipertensivi vârstnici 36 femei (56,25%) şi 28 bărbaţi (43,75 %) cu vârsta medie de 78,3 ani la care au fost normalizate valorile tensiunii arteriale prin internare în spital. Toţi pacienţii erau sub trata-

ment antihipertensiv şi cu valori ale tensiunii arteriale controlate (TA < 140/90 mmHg) la externare. Fiecare pacient a fost urmărit pe o perioadă de trei luni, prin măsurarea tensiunii arteriale de două ori/ săptămână dimineaţa şi seara şi de fiecare data când au apărut diferite simptomatologii (epigastralgii, cefalee, dureri reumatice, etc.). Determinarea TA s-a făcut după 5 minute de repaus în decubit dorsal sau poziţie şezândă, cu braţul la nivelul inimii, precum şi în ortostatism imediat şi la 2 minute după schimbarea poziţiei. Pacienţilor li s-a recomandat să nu consume cafea în ora precedentă examinării, să nu fumeze cu minimum 15 minute înaintea măsurătorii, să nu consume stimulente adrenergice exogene. Iniţial s-a determinat TA la ambele braţe, dacă TA era diferită la cele două braţe s-a folosit braţul cu TA cea mai mare. Ţinta pentru fiecare pacient a fost menţinerea valorilor tensiunii arteriale < 140/90 mmHg, prin modularea terapiei curente, sau prin adăugarea de noi agenţi antihipertensivi. Datele au fost procesate folosind programul *Microsoft Excel*.

REZULTATE

Vârsta medie a pacienţilor a fost de 78,3 ani, din care 36 femei (56,25%) şi 28 bărbaţi (43,75%), diagnosticaţi hipertensivi cu o vechime medie de 15,7 ± 13,5 ani, variind de la 1 an la peste 40 ani (fig. 1), având factori de risc asociaţi pentru sexul feminin: colesterol 37.2%; obezitate 24,5%; diabet zaharat 13,8%; antecedente heredo-colaterale 11,7%, iar la sexul masculin: colesterol 14,9%; obezitate 7,4%; diabet zaharat 3,7%; consum de alcool 78%; fumat 8,5%.

Valorile tensionale ale pacienţilor incluşi în studiu au fost sub 140/90 mmHg la externare, valori care au crescut în prima săptămână de la externare. Valoarea medie a tensiunii arteriale în prima săptămână de la externare a fost TAs (tensiune arterială sistolică) medie = 158,55 ± 17,06 mmHg iar TAd (tensiune arterială diastolică) medie = 81,57 ± 03 mmHg, valori care au scăzut în a doua săptămână dar fără a ajunge la valoarea ţinta de TA < 140/90 mmHg, media TAs = 153,20 ± 17 mmHg, iar media TAd = 80,05 ± 10 mmHg (tab. I). S-a semnalat un singur caz de puseu hipertensiv TA = 230/120 mmHg a doua zi de la externare şi două cazuri în care pacienţii au întrerupt intermitent medicaţia antihipertensivă.

Din punct de vedere statistic se evidenţiază diferenţe semnificative între valorile medii ale TAs şi TAd între cele 3 momente ale măsurătorii, cele mai mari diferenţe înregistrându-se între momentele externării şi prima săptămână, şi între prima săptămâna şi la 3 luni.

La includerea în studiu 38 pacienţi reprezentând 59,37 % primeau monoterapie, 19 pacienţi (29,69) biterapie iar 7 (10,94 %)

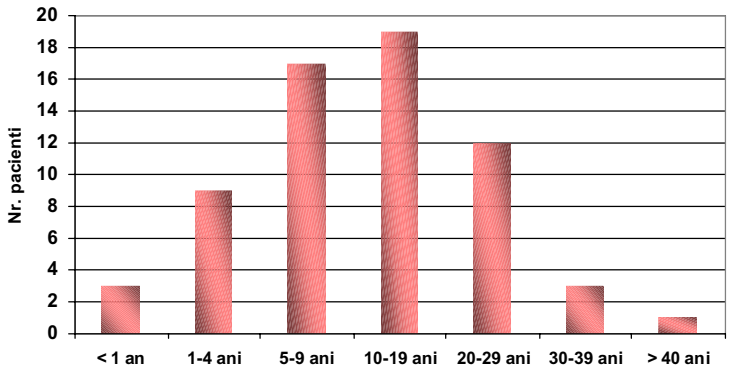

Fig. 1. Vechimea HTA

TABELUL I
Valorile TA pe parcursul studiului

	Externare	Prima săptămână	A doua săptămâna	Trei luni
TAs clinic	129,32±08	158,55±17,06	153,20±17	136,76±11,36
TAd clinic	74,76±16	81,57 ± 0,3	80,05±10	75,26±23

TABELUL II
Număr de pacienţi sub diferite scheme terapeutice

	Iniţial	Tratament ajustat
1 agent antihipertensiv	38	29
2 agenţi antihipertensivi	19	23
3 agenţi antihipertensivi	7	8
4 agenţi antihipertensivi	-	4

TABELUL III
Scheme terapeutice după clasele de medicamente antihipertensive

Monoterapie 29 pacienţi(45,31%)	IEC	22 pacienţi (34,37%)
	BB	5 pacienţi (7,81%)
	BCC	2 pacient (3,13%)
Biterapie 23 pacienţi (35,94%)	IEC+D	16 pacienţi (25%)
	IEC+BB	2 pacienţi(3,13%)
	BB+D	2 pacienţi (3,13%)
	BB+BCC	3 pacienţi (4,68%)
Tripla asociere 8 pacienţi (12,5%)	IEC+D+BB	5 pacienţi (7,81%)
	IEC+BCC+D	1 pacient (1,56%)
	BB+BCC+D	2 pacienţi (3,13%)
Cvadrupla asociere 4 pacienţi (6,25%)	IEC+BB+BCC+D	4 pacient (6,25%)

triplă asociere de medicamente antihipertensive. Modularea tratamentului s-a făcut după a doua săptămână de monitorizare clinică la domiciliu, după ce accentul s-a pus pe tratamentul nefarmacologic prin renunţarea la fumat, reducerea greutăţii corporale, reducerea sării din alimentaţie sub 2,4 g de Na, reducerea consumului de alcool, dietă echilibrată, bogată în produse vegetale (legume, fructe) şi săracă în grăsimi animale. Totodată s-a pus accent pe necesitatea administrării zilnice şi pentru toată viaţa a tratamentului HTA şi a beneficiilor pe care pacientul le are prin scăderea riscului de a dezvolta insuficienţă cardiacă, boli coronariene, tulburări de ritm, accident vascular cerebral, maladii renale şi reducerii riscului de deces datorită acestor maladii.

Alegerea drogului antihipertensiv s-a făcut după recomandările ghidului de diagnostic şi management al HTA al Societăţii Europene de Hipertensiune si al Societăţii Europene de Cardiologie din anul 2007, iar orarul administrării a fost ales după tipul diurn, vesperal sau susţinut al HTA, iniţial prin creşterea dozei de antihipertensiv aflat în schema de tratament (pentru creşterea complianţei la tratament), 43 de cazuri. La cei la care valorile tensiunii arteriale au rămas peste 140/90 mmHg şi erau cu monoterapie s-a adăugat un diuretic (9 cazuri -20,93%), la 5 pacienţi (11,63%) s-a adăugat al treilea agent antihipertensiv, iar la 4 pacienţi s-a adăugat al patrulea agent antihipertensiv. La 3 pacienţi (9,3%) nu a fost necesară ajustarea tratamentului (tab. II).

După ajustarea tratamentului şi după clasele de medicamente pacienţii au primit următoarele scheme terapeutice exemplificate în tabelul III.

Complicaţia cea mai frecventă a fost starea de deshidratare uşoară, prin scăderea senzaţiei de sete urmată de astenie, discrete tulburări urinare, tuse foarte rară, confuzii discrete sau fenomene de sedare. Pe perioada de apariţie a diferitelor simptomatologii (epigastralgii, cefalee, dureri reumatice) valorile tensiunii arteriale au avut o uşoară creştere cuprinsă între 5 -15 mmHg, motiv pentru care am decis numai tratarea simptomatologiei apărute. Asocierea inhibitori ai enzimei de conversie (IECA) + diuretic (D) şi IECA + blocante ale canalelor de calciu (BCC) nu au prezentat reacţii adverse creând impresia că tratamentul prescris este cel mai adecvat, motivând pacienţii al urma în dozele şi orarul stabilit.

La finalul celor trei luni de monitorizare clinică la domiciliu ,valorile tensiunii arteriale au fost controlate la un procent de 81,25% din pacienţii incluşi în studiu, cu valori ale TAs medie de 136,76± 11,36 mmHg, iar TAd medie = 75,26±17 mmHg. La 4 pacienţi nu s-a ajuns la valoarea ţintă a TAs cu toate că pacienţii aveau asociate patru clase de medicamente antihipertensive şi au fost trimişi la alte specialităţi pentru investigaţii suplimentare, iar 8 pacienţi nu au tolerat valori tensionale sub 150-160 mmHg acuzând cefalee, vertij sau astenie fizică.

DISCUŢII

Dacă la începerea studiului eram convinşi că vom reuşi controlul terapeutic al HTA la domiciliu apropiat de 100 la 100 considerând că rată scăzută de control al HTA la domiciliu se datorează dozelor insuficiente de medicamente antihipertensive, nerespectarea regimului desodat sau neadministrării medicaţiei recomandate, acest lucru nu a fost realizat ceea ce înseamnă că există şi alţi factori care duc la creşterea valorilor tensionale la domiciliu sau creşterea TA reprezintă un mecanism compensator pentru asigurarea nevoilor energetice mărite ale organismului faţă de condiţiile de repaus din spital.

Existenţa pacienţilor care nu tolerează valorile TA ţintă ne sugerează că scăderea Tas la aceste valori la unii hipertensivi vârstnici poate duce la hipoperfuzia diferitelor organe mai periculoasă decât valori ale TA de 150-160 mmHg.

În ceea ce priveşte clasele de medicamente şi orarul de administrare IECA administraţi seara în priză unică au determinat o scădere tensională nocturnă mai pronunţată decât după administrarea matinală şi a modificat favorabil profilul tensional al pacienţilor ; beta-blocantele (BB) au redus TAs şi a aplatizat ritmul circadian tensional şi a frecvenţei cardiace ; BCC au redus TA pe parcursul zilei şi nopţii atât la administrarea matinală cât şi vesperală ; diureticele au scăzut eficient valorile tensionale la pacienţii cu tensiune diurnă. Monoterapia a fost tratamentul cel mai acceptat de pacienţi, asocierile de agenţi antihipertensivi erau privite ca o agravare a HTA, aspect peste care pacienţii au trecut după explicarea beneficiilor care le comportă asocierea diferitelor clase de agenţi antihipertensivi. Din punct de vedere al complianţei la tratament pentru creşterea procentului de control terapeutic al hipertensiunii arteriale în populaţie îi revine medicului de familie (prin consiliere psihologică, reţete cu preţ scăzut), pacientului şi nu în ultimul rând, familiei pacientului ţinând cont că hipertensivul vârstnic este un pacient cu nevoi speciale.

Rezultatele studiilor : ALLHAT, VALUE, ASCOT, INVEST, COOPERATE, PROGRES aduc informaţii dovedite asupra importanţei tratamentului HTA, comparând eficacitatea şi beneficiul claselor de agenţi antihipertensivi prin reducerea TA per se precum şi beneficiul pe un organ ţintă. In ceea ce priveşte numărul de agenţi antihipertensivi, monoterapia poate fi tratamentul iniţial sau pe termen lung dacă valorile TA sunt ţinute sub control şi nu apar reacţii adverse, rezul-

tate obţinute şi în studiul nostru pe 29 pacienţi (45,31%). Beneficiile terapiei combinate, în studiul nostru pe 35 pacienţi (54,69 %), au fost demonstrate de majoritatea studiilor clinice mari (ASCOT, ALLHAT, INVEST) pentru obţinerea şi menţinerea valorilor ţintă ale TA, în special la pacienţii cu risc înalt, argumente aduse de studiul VALUE.

Beneficiile tratamentului antihipertensiv asupra protecţiei cardiovasculare sunt demonstrate şi de concluziile rezultate din meta-analiza efectuată pe cele 147 de studii clinice privind HTA publicate între anii 1966 şi 2007.

CONCLUZII

Scăderea TA la domiciliu spre valorile ţintă nu este tolerată de toţi pacienţii vârstnici, posibil asocierii leziunilor aterosclerotice, impunându-se o urmărire mai îndeaproape a acestor pacienţi

Orarul de administrare a medicaţiei antihipertensive trebuie să corespundă cu tipul de HTA (matinal, vesperal sau susţinut).

Iniţierea de măsuri pentru ajustarea schemei terapeutice şi creşterea complianţei la tratament.

Urmărirea în evoluţie, sesizarea complicaţiilor ce pot apărea la pacientul hipertensiv şi adoptarea atitudinii corecte de trimitere a pacientului la medicii de alte specialităţi.

Există pacienţi hipertensivi la care s-a normalizat TA în spital, dar fără a mai atinge valorile ţintă la domiciliu în pofida ajustării dozelor sau introducerii de noi agenţi antihipertensivi.

NOUTĂŢI

CANCERUL PANCREATIC

Articolul sintetizează progresele făcute în ultimii ani în înţelegerea mecanismelor moleculare, dar şi a diagnosticului, stadializării şi tratamentului pacienţilor cu cancer pancreatic în stadiile precoce. Cancerul pancreatic este rezultatul acumulării unor mutaţii genice successive. Acesta îşi are originea la nivelul epiteliului ductal şi evoluează din leziuni premaligne. Progresia de la o displazie epitelială minimă spre o displazie epitelială severă şi în final la cancer invaziv ar fi determinate de acumularea succesivă de mutaţii genice care includ : activarea oncogenei KRAS2, inactivarea genei supresoare de tumori *CDKN2A*, *inactivarea genelor supresoare de tumori TP53 sau DPC4*. Un studiu genetic recent pe 24 cazuri de cancere pancreatice a arătat că celulele canceroase pancreatice sunt purtatoare în medie de 63 de anomalii genetice per cancer, care pot fi grupate în 12 căi de semnalizare moleculare ; demonstrând astfel cât de eterogenă şi complexă este genetica acestui cancer. Cancerul pancreatic este caracterizat de prezenţa unei strome dense, slab vascularizate. Celulele pancreatice stelate joacă un rol important în formarea şi turnover-ul acesteia. Activate de către diverşi factori de creştere, celulele stelate secretă colagen şi alte componente ale matricei extracelulare. Celulele stromale sintetizează diverse proteine sau factori de creştere care au fost asociate cu un prognostic sumbru şi cu o rezistenţă la tratament. Acestea ar putea însă fi ţinte ale tratamentului în viitor. 1-5% din structura tumorii sunt celule cu proprietăăţi de celule stem, capabile de regenerare nelimitată. Aceste celule sunt rezistente la chimio si radioterapie ceea ce ar explica de ce acestea nu au beneficii în tratamentul bolii. O înţelegere mai bună a mecanismelor moleculare ale acestui cancer ar deschide noi posibilităţi de tratament de tipul unor molecule inhibitoare ale oncogenelor sau inhibitoare ale unor căi moleculare (RAS, Src sau MEK) anticorpi monoclonali contra unor proteine membranare de tipul mezotelinei, noi nanotehnologii sau agenţi adenovirali. Complexitatea şi eterogenitatea acestui cancer indică necesitatea unor tratamente individualizate (HidalgoM. Pancreatic cancer. *N Engl J Med* 2010, 362 (17) : 1605-1617).

THE TREATMENT OF ORGAN DYSFUNCTION IN HIV-POSITIVE PATIENTS (Abstract) **Aim:** To evaluate the clinical and viro-immunological status in order to manage multiple organ disfunction of HIV-infected patients admitted to Intensive Care Unit (ICU) during active antiretroviral therapy. **Material and Methods:** Retrospective study, using medical data of HIV infected patients from the Regional HIV/AIDS Center of the "Sf. Parascheva" Infectious Diseases Clinical Hospital Iasi, admitted to the ICU, between 1st January 2016-31 December 2018. **Results:** In this study were included 21 patients with different HIV/AIDS stages and a depressed clinical status requiring evaluation and monitoring in the ICU. They were predominantly male with an average age of 34 years old. The viral-immunological status revealed the CD4 lymphocytes value less than 50 cells/mmc for most of the cases (19 patients), and a viral load significantly increased. As opportunistic infections were recorded: Tuberculosis (8 cases), *Cryptococcal* meningitis (1 case), *Mycobacterium avium* infection (1 case), *Cytomegalovirus* infection (6 cases). The most common complications were: respiratory distress syndrome and bacterial pneumonia (8 cases); and severe sepsis (4 cases), being evaluated and surveilled in ICU. Nine patients needed oral tracheal intubation and vasopressor support. All patients received antiretroviral therapy in association with specific antibiotherapy or antifungals depending on complication. Only one case had favorable evolution, the rest of the patients died. **Conclusions:** The survival rate of HIV-infected patients admitted to the ICU was extremely low even if they had critical care for severe complications and opportunistic infections. **Keywords:** HIV-PATIENTS, ORGAN DISFUNCTION, HAART, INTENSIVE CARE TREATMENT.

Human Immunodeficiency Virus (HIV) infection is an important medical problem all over the world. The latest global statistics show that in 2017 there were 36.9 million people living with HIV. From this number, 34.5 million are adults, 17.8 million young girls (over 15 years old). Worldwide, approximately 1.8 million people were newly infected, and about 1 million people died each year from AIDS-related illnesses. In December 2017, 21.7 million people living with HIV were accessing antiretroviral therapy (1).

In the United States, about one million people are infected with HIV. There are about 40,000 to 60,000 new cases of HIV infection each year (2).

In Eastern Europe and Central Asia, there were 1.8 million people living with HIV in 2017, and in the same year about 40,000 people died of AIDS-related illnesses (1).

The epidemiological profile of patients with HIV infections is shifting in different

countries. There are a significant number of homosexual males who are infected in large urban areas, but there is a growing proportion of infected patients who are women who live in smaller cities or rural areas and who have acquired their infection heterosexually or via intravenous drug abuse (2).

The general report for Romania, showed a total of 23,302 cases of HIV/AIDS in 30 June 2018, of which 15,212 are living with HIV, about 257 people newly diagnosed and 68 deaths in the last year (3).

The population of HIV-infected patients is also getting older: patients with HIV infection benefit from improved management and live longer. Individuals without HIV infection are also living longer, and are sexually active longer, extending the period of risk for acquiring HIV infection.

Opportunistic infections occur in HIV-positive individuals as their immune system weakens and the etiology of the infectious organism is affected by the immunological status of the patient. In more economically developed countries, due to the extensive use of highly active antiretroviral therapy (HAART), infections like *Cytomegalovirus* (CMV), *cryptosporidiosis* and *toxoplasmosis* predominate. However, in developing countries, infections due to *Mycobacterium tuberculosis* are more common.

But given the importance of this pathology and combining various complications, some HIV-positive patients require intensive care in some critical moments. The HIV-infected patients are admitted in Intensive Care Unit (ICU) for different reasons. Some reasons are related to clinical issues related directly to HIV infection, such as opportunistic infections. As opportunistic infections have declined, the proportion of hospitalizations due to respiratory diseases, next to hepatic, renal, and cardiovascular disease has increased (4). Several antiretroviral agents have toxicities that can present pulmonary or respiratory manifestations.

When patients receive antiretroviral therapy that contain abacavir, they can develop a hypersensitivity syndrome that is difficult to distinguish from nonspecific febrile respiratory illnesses (5, 6). When HIV-infected patients are admitted to the ICU, a major issue is whether to continue their antiretroviral therapy or stop the drugs (2).

The aim of this study was to evaluate the clinical and viro-immunological status in order to manage HIV-infected patients admitted to ICU during the era of highly active antiretroviral therapy (HAART).

MATERIAL AND METHODS

We performed a retrospective study, using data from medical records of HIV infected patients from the Regional HIV/AIDS Center of the "Sf. Parascheva" Infectious Diseases Clinical Hospital Iasi admitted to the Intensive Care Unit of the same Hospital, between 1st January 2016 - 31 December 2018.

RESULTS

Of a total of 1,544 HIV-positive registered in the Iasi HIV/AIDS Regional Center, in the studied period were included 21 patients with different HIV/AIDS stages (18 cases C3 AIDS and 3 patients with stage B2 HIV seropositive) who were hospitalized in the Regional HIV/AIDS Center of Infectious Diseases Clinical Hospital Iasi, and whose clinical status was depressed requiring evaluation and monitoring in the Intensive Care Department.

The patients were clinically, biologically, serologically, bacteriologically, viro-immunologically and imagistically evaluated.

They were predominantly male, with an average age of 34 years, from urban area (tab. I).

Most of the cases were patients from pediatric cohort. The clinical condition from

admission was severely influenced, most of them had fever, tachycardia, tachypnea, hypoxia (tab. II).

TABLE I
Patients characteristics

Patients characteristics	Number of cases
24-30 years old	13
30-40 years old	3
> 40 years old	5
Male	18
Female	3
Urban area	11
Rural area	10
C3 AIDS stage	18
B2 HIV seropositive	3

TABLE II
Patients clinical status

Clinical status	Number of cases
Fever (t > 37.8˚C)	12
Asthenia	8
Tachycardia (> 90/min)	13
Tachypnea (> 20/min)	15
Hypoxia (PaO_2/FiO_2 < 280mmHg)	16
Dry cough	9
Oliguria	5
Confusion syndrome, aphasia	5
Meningeal contracture syndrome/neck stiffness	7
Wasting syndrome	4
q SOFA (quick Sepsis Related Organ Failure Assessment) score 2-3	4

The viral-immunological status revealed a value for CD4 lymphocytes very low from 1 to 275 cells/mmc, for most of the cases (19 patients) the CD4 value was less than 50 cells/mmc (fig.1).

Also, the viral load was significantly increased, the highest one was 5 million IU/mL (fig. 2), in accordance with the HIV patient's condition.

There were cases where viral loads recorded values between 50,000 copies/mL and 72,000 copies/mL with CD4 T cell counts, below 100 cells/mmc, especially for *late presenters* HIV-positive patients.

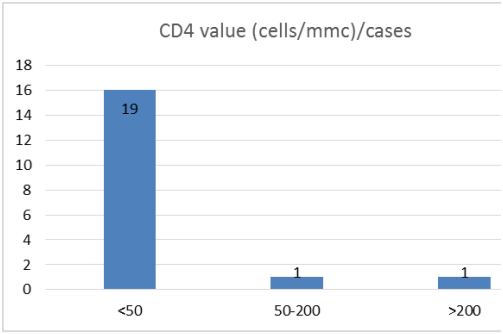

Fig. 1. Cases distribution by CD4 value (cells/mmc)

The serological tests have most frequently revealed hepatitis B virus infection and cytomegalovirus infection (Ag HBs - 6 cases, anti HCV antibodies – 2 cases, anti-*Toxoplasma gondii* (IgM/IgG) antibodies - 2 cases, anti-*Cytomegalic virus* (IgM/IgG) antibodies – 6 cases). Anti-*Treponema palladium* antibodies were positive in 4 cases.

As opportunistic infections were recorded: Tuberculosis (8 cases), *Cryptococcal* meningitis (1 case), *Mycobacterium avium* infection (1 case), *Cytomegalovirus* infection (6 cases), (fig. 3).

The blood culture did not revealed bacterial growth after 7 days of incubation. The lingual scrape revealed *Candida sp.* in most of the cases (10 cases).

Pulmonary tuberculosis was diagnosed in 8 cases by chest radiography, the sputum exam highlighted the presence of acid-alcohol resistant bacilli, and also *Quanti-Feron-TB Gold* tests were positive, followed by pneumological evaluation for mycobacterial culture and antituberculosis regimens.

There were also two cases of C3 stage AIDS disease that have associated tuberculosis with extrapulmonary localization: the lymph node and abdomen.

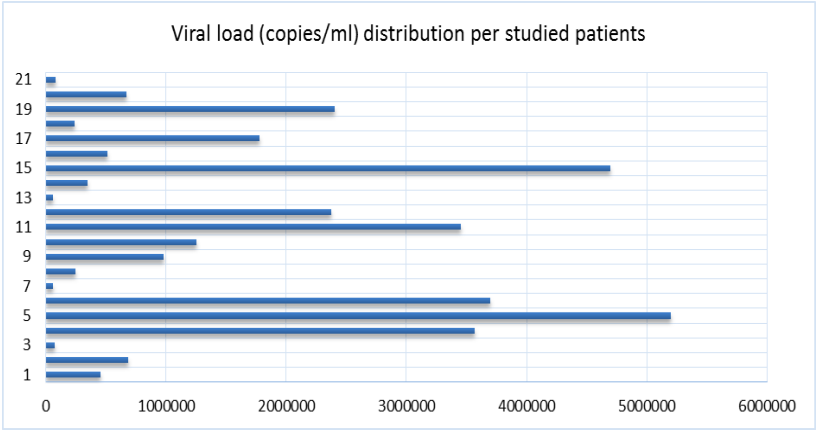

Fig. 2. Cases distribution by viral load value (IU/mL)

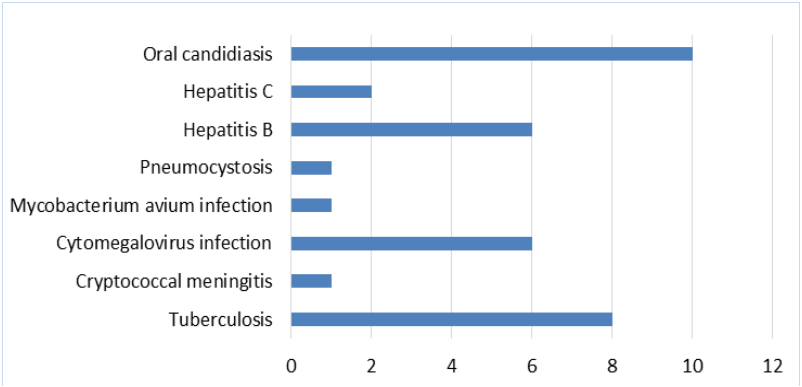

Fig. 3. Cases distribution by opportunistic infections

In one case, the diagnosis of cryptococcosis meningitis was established by examination of cerebrospinal fluid (CSF): 7 ecn/mmc, albuminorachia = 0.55g/L, glycorrhachia = 34g/L, chlororurachia = 6.65g/L, and *Cryptococcus neoformans* was identified in the fungal culture of the CSF. Also, the meningoencephalitis was recorded in 6 cases. In four cases cerebral malignant lymphoma was associated.

The most common complications were respiratory distress syndrome and bacterial pneumonia in HIV-positive patients with pulmonary tuberculosis (8 cases), and other cases had severe sepsis criteria associated with multiple organ dysfunction, with qSOFA (quick Sepsis Related Organ Failure Assessment) score: 2-3 (4 cases).

Clinical evolutive status was correlated with hepatic and renal failure, in association with dyselectrolytemia, and hypoproteinemia, subsequently patients needed assistance, evaluation and monitorization in Intensive Care Unit. Seven patients required oral tracheal intubation, 11 patients needed vasopressor support.

All patients required antiretroviral therapy in association with specific antibiotherapy or antifungals (most common was: Fluconazole, Anidulafungin, Itraconazole), depending on complication*: Candidiasis*, *Cryptococcal* meningitis, according to anti-

fungal susceptibility testing.

Also, in same cases was used nebulized polymyxin E (Colistin) for treatment of multidrug-resistant pneumonia, or in order to prevent it. Also, antituberculosis therapy was needed in treatment of pulmonary tuberculosis in 8 patients. The trimethoprim/ sulfamethoxazole was used for prophylaxis of pneumocystosis (tab. III).

The association of antibiotics was based on complications or opportunistic infections, in order to avoid drug interactions (antiretrovirals and antibiotics), as Liverpool HIV Interactions (7) require.

TABLE III
Therapy used

Antibiotic regimens used
Cephalosporins/Carbapenems + Fluoroquinolones/Aminoglycosides
Cephalosporins + Trimethoprim/sulfamethoxazole
Antituberculosis therapy

Two patients registered adverse reaction to antiretroviral therapy. The average hospitalization period was 14 days. Only one case had favorable evolution, the rest of the patients died.

DISCUSSION

In the current context of HAART, the complications that require critical care support in intensive care units (ICU), are still present, being a serious medical problem. The respiratory failure was the leading cause of ICU admissions among HIV-infected patients, followed by sepsis and neuro-oncological disease. The most affected age was the young age of patients coming from the Romanian pediatric cohort. The CD4 lymphocyte count in the patients that required admission in ICU, was very low, being associated with suppressed cellular immunity, and its association with increased mortality has also been demonstrated in prior studies (8, 9). Other studies that were conducted in European countries, also had the same causes of ICU admissions observed in our study (10). Sepsis and higher rate of mortality in the seropositive HIV patients was associated also in previous studies (8, 11-13). Co infection HIV/HCV has become a major cause of morbidity and mortality among seropositive HIV patients in HAART's era (14, 15), but in our study most of the cases were coinfection with hepatitis B virus, and in few cases hepatitis C virus was involved (15). Neurological disorders: malignant lymphoma and meningoencephalitis were noted especially on pediatric cohort like in other studies has been showed (16). The most commonly used antiretroviral regimens included rescue therapies with the administration of two protease inhibitors in combination with two nucleoside reverse transcriptase inhibitors, as previous studies described (17). The high mortality rate of HIV seropositive patients requiring monitoring in intensive care was also recorded in other previous similar studies (10, 12, 18). Our study was limited to reported cases of seropositive HIV patients in the Moldavian area.

CONCLUSIONS

The collaboration with intensive care unit was absolutely necessary in order to manage the complications and opportunistic infections in HIV-infected patients. The survival rate of HIV-infected patients admitted to the ICU was extremely low even if they had critical care for severe complications of HIV infection or for conditions related to HAART toxicity.

ACKNOWLEDGEMENTS.

We thank to HIV/AIDS Regional Centre for possibility of accessing medical record of HIV-infected patients.

BETABLOCKERS AND VARICEAL BLEEDING IN PATIENTS WITH DECOMPENSATED LIVER CIRRHOSIS

BETABLOCKERS AND VARICEAL BLEEDING IN PATIENTS WITH DECOMPENSATED LIVER CIRRHOSIS (Abstract): It is well known that nonselective betablockers (NSBBs) reduce the risk of first bleeding and rebleeding from esophageal varices in liver cirrhosis. Recent studies suggested that in decompensated cirrhosis NSBB can be harmful and can increase mortality, so they should be used only in the "therapeutic window". This article summarizes the data regarding the role of NSBBs in the prevention of variceal bleeding, focused on decompensated liver cirrhosis and its complication. Ascites per se is not a contraindication for NSBBs, but if ascites is severe or refractory it is better to avoid high propranolol doses (>80 mg). The treatment must be discontinued when the patient with decompensated liver cirrhosis develops signs of circulatory dysfunction: arterial hypotension (systolic blood pressure <90 mmHg), renal failure (serum creatinine >1.5 mg/dL) or when Na<130 mEq/L. In spontaneous bacterial peritonitis and acute on chronic liver failure, NSBBs have favorable effects independent of decreasing the hepatic venous pressure gradient. **Keywords**: DECOMPENSATED LIVER CIRRHOSIS, NON-SELECTIVE BETABLOCKERS, BLEEDING.

Liver cirrhosis (LC) of any cause is a complex disease with high mortality. In USA it is the fifth leading cause of adult deaths and ranks eighth in economic cost among major illness; in Europe it accounts for 1.8% of all deaths (1). According to WHO there are 30 annual deaths per million population and the global average is 2.4 deaths per million (1). Romania is one of the European countries with the highest prevalence and mortality rate (36 per 100,000) (2).

At present, as the treatment of liver diseases causes substantial economic burden globally, we can rightly ask ourselves if there is a drug that is cheap, easy to use and has a large utility in chronic liver disease which could determine a decrease in the severe complications and thus to improve the quality of life and survival (3).

In 1981 Lebrec (4) demonstrated that Propranolol, a non-selective β-blocker (NSBB), reduced the risk of bleeding and rebleeding from esophageal varices in LC

and it was used until 2010 without other debates (5). We must mention that almost all studies in the literature excluded patients with advanced LC. In 2010 Serste (6) published a study which demonstrated that patients with refractory ascites on propranolol had a poorer survival rate than those who were not on NSBBs. Latest studies showed contradictory correlation between NSBBs and mortality in advanced LC (7, 8). In 2012, Krag (9) proposes "the window hypothesis" that implies the existence of a therapeutic window for NSBB treatment which closes late in the natural course of cirrhosis. Krag suggested that NSBBs are effective only within the "therapeutic window". Outside the "therapeutic window" β-blockers may be ineffective and unfortunately are potentially harmful in advanced cirrhosis.

It is well-known that portal hypertension (PH) is the initial consequence of LC and it is responsible for the majority of its complications. Patients with compensated LC can be divided into two groups based on portal pressure (PP). If PP is between 5 and 10 mmHg the patients have mild PH. When PP is >10 mm Hg the patients have clinically significant PH (CSPH) (10). CSPH is associated with an increased risk of developing varices, clinical decompensation (ascites, variceal bleeding, hepatic encephalopathy) and hepatocellular carcinoma (HCC) (11-13). CSPH is an independent predictor of decompensation in patients with compensated LC. The patients with CSPH can also be divided into two groups: with and without gastroesophageal varices (10). Management of varices and variceal hemorrhage must be considered in the context of other complications of cirrhosis. In patients with CSPH and varices one of the main goals is to prevent variceal hemorrhage and decompensation. β-blockers (propranolol, nadolol and carvedilol), decrease PH and prevent the occurrence and recurrence of variceal bleeding (10).

Currently, carvedilol, a NSBB with mild α-1 adrenergic activity, is preferred. Carvedilol is more effective in reducing hepatic venous pressure gradient (HVPG) due to α-1 blockage and by that it reduces intrahepatic resistance in decompensated LC in patients with severe dysfunction. The main adverse effect compared with propranolol is the severe decrease of mean arterial pressure which leads to poor organ perfusion in one third of patients (14).

Due to the mechanism of PH reduction, NSBBs have been proved to be effective in the prophylaxis of variceal bleeding. The AASLD guideline and Baveno VI recommend it for primary and secondary prophylaxis (15, 16).

PREVENTION OF FIRST VARICEAL HEMORRHAGE

Studies have demonstrated that NSBBs prevent first hemorrhage both in compensated and decompensated LC patients with esophageal varices (10, 17). Ponyard *et al.* (17) demonstrated that the first variceal bleeding was significantly reduced not only in patients without ascites, but also in those with ascites. In Garcia-Tsao study (10) the risk of first hemorrhage was significant lower in patients receiving NSBBs compared with those receiving placebo even if their Child-Pugh score was higher than 8 (Class C). In their study, D'Amico *et al.* (18) demonstrate that NSBBs are reliable to use for the primary prophylaxis, reducing the risk of first bleeding by 10%. However, NSBBs do not reduce the mortality risk in patients with medium-large varices when

NSBBs are used for primary prophylaxis. Opposite, when used for secondary prophylaxis they reduce the risk of rebleeding by 21% and also the mortality risk (18). Gluud and Krag (19) demonstrate that, for medium and large varices, NSBB prophylaxis is as efficient as esophageal variceal band ligation (EVL).

In patient with large varices NSBBs are also effective. Villanueva *et al*. (20) demonstrated that the reduction of HVPG >10 mmHg improves the outcome. The authors reported a significant reduction of first bleeding and mortality by using NSBBs in patients with large varices (20). More than that, Hernandez-Gea *et al*. (21) demonstrated that the responders (a reduction in HVPG of ≥10 mmHg) had a lower probability of developing ascites. Finally, for clinical practice purpose, we must know that β-blockers can be successfully used in prevention of the first variceal hemorrhage. The following categories of patients can benefit from this prevention: patients with high risk of hemorrhage: medium/large varices, any size varices with red wall marks and any size varices in Child C patients. In patients with or without ascites, β-blockers are the first line of treatment for preventing the first hemorrhage episode; if the patient is β-blocker intolerant, band ligation is recommended, according to local expertise and patient preference (21).

PREVENTION OF REBLEEDING IN LIVER CIRRHOSIS

In a systematic review, Puente (22) demonstrated that the addition of drug therapy with β-blockers ± isosorbide mononitrate to EVL significantly improves the efficacy of EVL, achieving a significant reduction of rebleeding risk. The beneficial effect of combination therapy was observed on both variceal rebleeding and overall rebleeding.

A number of studies have demonstrated that reducing portal pressure with NSBBs to <12 mmHg or ≥ 20% from baseline value decreases rebleeding risk in less than 10% of the cases (23). In the β-blocker-responsive patients (decrease of HVPG <12 mmHg) bleeding episodes and death rate are significantly lower. Besides that, some studies have demonstrated that reaching these targets are associated with a significant decrease in the risk of developing other PH-related complications such as ascites or hepatorenal syndrome and significantly improves survival (24). Garcia-Tsao also demonstrated that the combination NSBB + ligation is associated with lower rebleeding rates (15). For clinical practice we must know that for prevention of rebleeding – ascites is not a contraindication (15, 23). First line therapy for all patients is combination of NSBB (propranolol or nadolol) + EVL, NSBB being the key element of this combination, acting in a physiological manner (15). Carvedilol is not recommended is secondary prophylaxis. If variceal bleeding occurs while on adequate NSBB dose the patient is considered no responder and should be evaluated for trans jugular intrahepatic portosystemic shunt (TIPS), surgery or transplantation (15, 16).

HOW TO USE BETABLOCKERS IN PATIENTS WITH ASCITES?

Ascites per se is not a contraindication for NSBBs. If ascites is severe or refractory it is better to avoid high dose propranolol (>80 mg) and the use of carvedilol, because it can determine sever decrease of mean arterial pressure and poor organ perfusion (24).

The manner in which β-blockers are

administered in patients with ascites is also important. In these patients low-dose (≤80 mg/day) propranolol administrated step by step is preferable. All these measures improve tolerance and reduce side effects until maximum tolerated dose is reached. For example, propranolol is thus administered: first week: propranolol 20 mg in the morning and in the evening; second week: 20 mg in the morning and 40 mg in the evening, third week: 20 mg in the morning and evening; fourth week (if is well tolerated): 40 mg in the morning, 20-40 mg at lunchtime, 40 mg in the evening (15, 25).

The treatment must be stopped when the patient with decompensated LC develops signs of circulatory dysfunction: arterial hypotension (systolic blood pressure < 90 mmHg), renal failure (serum creatinine >1.5 mg/dL) or when Na< 130 mEq/L (15, 16, 26). Moreover, when hepatorenal syndrome or hemorrhagic shock occur, terlipressin or vasopressors should be used. When arterial hypotension occurs, studies (15, 23) recommend to find and treat other causes of arterial hypotension (infections), reduce the NSBB doses and then discontinue the treatment and monitor blood pressure changes. When severe hypoalbuminemia (<25 g/dL) is present, plasma expansion must be used. In primary prophylaxis of variceal bleeding, studies recommend to switch from NSBB to EBL and in secondary prophylaxis it is advisable to try to maintain low propranolol dose.

BETA-BLOCKERS AND SPONTANEOUS PERITONITIS

Thalheimeire *et al.* (26) proved that in cirrhotic patients β-blockers decrease bacterial translocation from the gut by diminishing splanchnic blood flow - secondary to reducing intestinal mucosal edema and congestion and increasing intestinal transit stimulation (β-adrenergic receptor-mediated pathway) (27). NSBB also enhances the immune system by inhibiting the stress-related cyclic adenosine monophosphate-protein kinase which has an inhibitory effect on the immune system (28) and significantly decreases the incidence of postsurgical laparoscopic infections (29).

In spontaneous bacterial peritonitis (SBP), β-blockers reduce infections and improve survival, this way preventing other complications of cirrhosis, at doses of up to 160 mg/day. If in SBP severe hypotension (systolic blood pressure < 130 mmHg) and alteration of renal function do occur, β-blockers must be administered in a lower dose or stopped. They may be reintroduced after correction of kidney and circulatory dysfunction, in order to prevent recurrent hemorrhage (28). β-blockers reduce infections and improve survival independent of the prevention of bleeding and hemodynamic response; it is still not entirely clear if NSBBs can prevent the occurrence of SBP in cirrhosis with ascites (NSBB treatment ↓ bacterial translocation) (28, 29).

NSBB AND ACUTE ON CHRONIC LIVER FAILURE

Acute on chronic liver failure (ACLF) is a complication of liver cirrhosis characterized by acute deterioration of liver function, multiple organ failure and high mortality. Its main characteristic is systemic inflammation. The severity of ACLF is an independent predictor of mortality**.** It is known that NSBBs have beneficial effects on gut motility reducing bacterial translocation, permeability and systemic inflammation. Ustundag (30) reported for the first time that ongoing treatment with NSBBs in

cirrhosis is safe and reduces mortality if patients develop ACLF, reducing inflammation. Mookerjee (31) demonstrated that NSBBs reduce short time mortality (28 days) but do not improve long time mortality**.** The administered dose was 40 mg (20-80 mg) -lower than in previous studies- and the conclusion of the study is that ongoing administration of NSBB is safe, cheap and effective in cirrhotic patients developing ACLF.

CONCLUSIONS

Revising the medical literature, combined with clinical practice, we can conclude that NSBBs remain the best prophylactic treatment for first bleeding in patients with decompensated LC. Ascites per se is not a contraindication but, if ascites is severe, avoid high dose of propranolol (>80 mg) and do not use carvedilol. For secondary prophylaxis of bleeding the standard therapy consists in a combination of a NSBB (propranolol or nadolol, not carvedilol!) and EVL. In severe circulatory dysfunction (blood pressure < 90 mmHg, creatinine > 1.5 mg/dL, Na<130 mEq/L) propranolol should be stopped. We must try to restart Propranolol with progressive doses (mainly to prevent rebleeding). Due to reduction in bacterial translocation and decreasing the systemic inflammation NSBBs have also beneficial effects in other complications of LC: SBP and ACLF.

TUBERCULOSIS: BETWEEN THE OLD AND THE NEW (Abstract): Isoniazid, rifampicin, ethambutol and pyrazinamide are administered in combination for at least 6 months in pulmonary tuberculosis (TB) -one of the first causes of death worldwide- and represent the first-line antituberculotic drugs, with different mechanisms of action, efficacy and toxicity. The susceptibility of the mycobacterial subpopulations to chemotherapy can be affected in immunocompromised patients so a systemic infection, post-primary, latent or even multidrug resistant is then activated. There is an urgent need to develop new drugs or to repurpose existing ones, that have not yet been tested for their antimycobacterial activity. Moreover, the only available antitubercular vaccine does not imply protection against adult lung active TB, the most prevalent form. Additionally, the only new antitubercular agents approved in the last years - bedaquiline and delamanid - have not provided satisfactory results in eradicating this ancient disease. Recent studies have shown surprising information regarding the use of statins in TB, indicating that they limit the mycobacterial growth by promoting autophagy and apoptosis in macrophages and by inhibiting the synthesis of cholesterol, the precursor of the virulence factors. Other new findings in TB management include the beneficial effects of vitamin D supplementation, with increased healing rates, high bacterial toxicity and the observed decrease of resistant strain selection, when using phenothiazines in coadministration with isoniazid. **Keywords:** TUBERCULOSIS, STATINS, PHENOTIAZINES, BEDAQUILINE, VITAMIN D.

Despite all the efforts to eradicate it, tuberculosis (TB) remains today one of the leading infectious causes of death and a major health issue worldwide (1). It is caused by *Mycobacterium tuberculosis*, a member of a bacterial complex which also includes other species such as *M. bovis*, *M. africanum*, *M. caprae*, *M. microti* and *M. canettii*, most of them having the ability to trigger the disease mostly in humans (2-4).

Although pulmonary TB has the highest prevalence, in adults, as well as in children, the disease can also be extra-respiratory, affecting other organs – such as skin, bones, genitourinary tract, pericardium, abdomen - including the head and neck region (face and neck lymph nodes, thyroid, larynx, pharynx, salivary glands, tongue, mandible and buc-

cal mucosa) (5-11).

According to the World Health Organization (WHO) there are more than 10 million new cases of TB every year and it represents one of the first ten leading causes of death in the world and the leading death cause in patients with human immunodeficiency virus (HIV) (12), but the global mortality rate is falling at 3% every year (13) due to the fact that TB is treated with at least 6-months regimen of four first line-drugs (isoniazid, rifampicin, ethambutol and pyrazinamide) and not by drinking water, staying isolated, outside in fresh air, as they used to treat it before the first discoveries of streptomycin in 1944 and isoniazid in 1952 (12, 14, 15).

This highly threatening TB additionally possesses serious economic risks worldwide because it affects mostly individuals between 25-45 years old, which means it affects their most productive period of life (8,13). Mycobacterium can be contracted from humans or from animal hosts and it becomes more dangerous in immunosuppressed people (14, 16). Patients with sputum smear-positive are usually diagnosticated with pulmonary TB which affects the lungs and is the most contagious form of the disease because the bacteria is expelled by coughing into air-droplets, also called Flugge's drops, but it can also affect extrapulmonary sites (2, 14).

PHARMACOTHERAPY

Once active disease is manifested, 4 *first-line drugs,* with different mechanisms of action, are administered for 2 months, as an intensive phase, and for 4 months, as a continuation phase, in new TB cases; respectively, for 8 months, as an intensive phase, and 12 months, as a continuation phase, in previously treated cases, when a first treatment failure is present (3, 17, 18). Monotherapy with isoniazid can be used, for 9 months, but only in asymptomatic patients with latent TB (3, 16, 19).

To understand how to manage TB treatment, it is important to distinguish between different populations of *M. tuberculosis*, which react to various antibiotics, because *M. tuberculosis* has a slow response towards treatment, due to its capacity to form heterogenous bacterial populations and its different mechanisms of adaptation to the environment and because M. infection presents like a polymicrobial infection (4, 18, 20, 21). Subpopulations are structured by their drug tolerance or their location and they are composed of actively growing bacteria, slow or non-replicating bacteria, intracellular bacilli present in the acidic compartments of macrophages or lesions and bacilli that persist in hypoxic areas, the last ones representing the main cause of multi-drug-resistance tuberculosis (MDR-TB) (20).

Traditional anti-TB drugs

First-line drugs are different from second-line because of their efficacy over the actively replicating bacteria, activity and toxicity: isoniazid, rifampicin, ethambutol, pyrazinamide, the first two representing the most active and the most important antimycobacterial drugs, but also the ones to which MB first gains resistance (3, 16, 20). The combination of isoniazid-rifampin will cure more than 95% cases, in 9 months, but if neither isoniazid or rifampicin can be used due to prevalence of 3% resistance to both, treatment will encounter a prolonged phase for more than 2 years, the patients risking toxicity and adherence issues (14, 16).

Isoniazid is an enzyme inhibitor, highly specific for mycobacteria, which has a

similar structure to pyridoxine (vitamin B_6) and is a prodrug that inhibits mycolic acid synthesis, by covalent binding, meaning it affects the bacillus cellular wall (12, 14, 16, 22). It has bactericidal effect in dividing cells but is bacteriostatic in resting cells (3, 14). One of the most important adverse reactions is clinical fatal hepatitis which can occur in 1% patients, especially for those aged 50 or older, treated with isoniazid (2, 14). Less common, in patients with pyridoxine deficiency, are central nervous toxicity and hematologic issues, but they can be prevented by recommending 25 mg of pyridoxine with each oral dose of isoniazid, as also for pregnant women, alcoholics and patients with poor regimen of life (1, 3, 14).

Rifampicin, an antibiotic produced by a species of *Streptomyces*, introduced in the early 1970s as one of the most active antituberculotic drugs, has a sterilizing bactericidal action over slow or non-replicating subpopulations of *M. tuberculosis*, a bacilli that adapt so well to dynamic surroundings, and has represented a success in reducing the length of treatment, from 18 months to only 6 months, which means reduced toxicity and increased adherence (3, 14, 17). Rifampicin binds to the β subunit of bacterial DNA-dependent RNA polymerase and inhibits RNA synthesis, easily penetrating phagocytic cells and engulfing the bacilli (12, 14). It is active against intracellular organisms from lung cavities and it is usually administered orally in 600 mg dosage, daily or twice a week, but it can also be administered intravenously, when it is metabolized to also active rifampin (3, 14, 23). Unlike isoniazid as enzyme inhibitor, rifampicin is a potent inductor of the cytochrome P_{450}, so other treatments in TB patients such as antiretroviral or contraceptive should be reconsidered (14, 16, 21). The half-life of rifampicin is 1 to 5 hours, which shortens after a period because of induction of hepatic enzymes (2, 14). HIV patients generally receive rifabutin in a 300 mg/day dosage, instead of rifampicin, due to its lower capacity to induce microsomal activity, but, unfortunately, rifampicin-resistant organisms are also resistant to rifabutin (8, 14, 16). Adverse reactions include skin rashes, occasionally hepatitis and liver damage, nephritis and, if administered less often than twice weekly, it may cause a flu-like syndrome characterized by sweats, chills, fever, myalgia and thrombocytopenia, so patients should be warned not to skip doses (3,14). Rifapentine is an analogue of rifampin, also a bacterial RNA polymerase inhibitor, a potent enzymatic inducer and it is indicated only in rifampin-susceptible strains during the continuation phase, after 2 months of treatment (14, 16). Rifapentine should not be used in HIV infection because it gives high relapse rate with rifampin resistant organism (14, 19). Although cross-resistance with other drugs is not usually a problem, resistance can develop rapidly from a chromosomal mutation, as well as in isoniazid case when a gene mutation is involved (2, 3). Medical products exist to prevent resistance and to increase the patient's compliance for the treatment, such as fixed-combination with rifampin 120 mg, isoniazid 50 mg and pyrazinamide 300 mg, in a classic dosage of 5 to 6 tablets per day (3,22).

Because specialists cannot count differentiated populations of *M. tuberculosis* within a given patient, a multi-drug treatment is used not only with isoniazid and rifampicin, but also with *pyrazinamide* which appears most active against organisms from caseating granulomas, in an

acidic pH, in almost dormant state, with occasional bursts of metabolic activity (3, 17). When entering the lung delimited zone of the bacillus, pyrazinamide turns into pyrazinoic acid, the real active compound, through specific mycobacterial enzymes where it inhibits bacterial fatty acid synthesis (2, 3, 14). These actions represent a specific in vivo sterilizing mechanism, pyrazinamide requiring incubation within an acidic pH, found to lack under in vitro conditions (22). It has a half-life of 11 hours, is intestinally well absorbed and widely distributed in the tissues. Pyrazinamide relies on a hepatic clearance, so hepatic adverse events such as elevations of serum transaminases can occur. Similar to other first-line drugs, pyrazinamide treatment can also be associated with nausea, fever, fatigue, dark urine and pale feces, hyperuricemia with even gouty arthritis (3,14). The hyperuricemia that occurs with pyrazinamide does not respond to usual antigout medicine, in comparison with ethambutol.

Ethambutol is a specific antituberculotic agent, always given in combination with other antituberculotic drugs, in a 50 mg/kg twice a week dosage and it inhibits mycobacterial arabinosyl transferases which are involved in the intracellular synthesis of arabino glycan, the essential component of the bacillus wall (14). Ethambutol also has a bacteriostatic effect by inhibiting the synthesis of polyamines which are necessary for the normal DNA function (3, 12), is well absorbed from the gut and its maximum peak levels are reached in 2-4 hours (2, 14). It is one of the most efficient drugs in TB meningitis, without difficulty crossing the blood barrier in meningeal inflammation (2). It accumulates in renal failure due to its unchanged form in renal excretion and it can cause retrobulbar neuritis, loss of visual acuity and red-green color blindness, if administered for more than several months. Fortunately, the visual neuritis is reversible on the rapid discontinuation of the treatment (3). This is the reason why ethambutol is contraindicated in children under 6 years old (3, 14).

Resistance and cross-resistance

WHO recommends a directly observed treatment, short-course strategy (DOTS) to control tuberculosis which encourages the supervision and the direct observation of a healthcare worker for the patients in order to maintain their adherence (13, 17). The granulomatous tissue in TB, earlier discussed, is an ordered cellular architecture, structured with epithelioid cells and fibroblasts, surrounded by lymphocytes, known as Langhan's cells, which remain stable for months or even years, until lymphocytes are requested in other immune processes (9, 20, 23, 24). Necrotic dynamic lesions are formed and when the destruction reaches the bronchi, a cavity appears and its degree determines the failure of the treatment (18, 20). As a response, this affects the susceptibility of the mycobacterial subpopulations to chemotherapy so a systemic infection, post-primary, latent or even multi-drug resistant is then activated in the immunocompromised patients with the appearance of extensively multi drug resistant tuberculosis (XDR TB), mostly present in HIV co-infected patients (8, 18, 23, 25). In 2017, 558,000 people developed TB that was resistant to rifampicin, the most effective first line drug, and of these, 82% had MDR-TB, found particularly in India, China and Russia, which represented an increase from 2016 cases (13). Even though there is no standard regimen for

MDR cases, second-line tuberculostatic treatment is used for drug-resistant TB, but it is important to mention that is critically necessary to avoid monotherapy and from the other point of view, *streptomycin, kanamycin and amikacin* as well as *fluoroquinolones* may cause fetal ototoxicity and fetal growth problems and they should not be used in pregnancy or children with TB (3,17). The inherent toxicity of second-line drugs used in MDR-TB is also demonstrated by the fact that *cycloserine* may cause paranoia, confusion, depression, photosensitivity and sun precautions should be taken, *prothionamide* may trigger arthralgia and myalgia, aminoglycosides affect the kidney and vestibular functions and in all cases liver function should be monitored (2,3,20). In XDR-TB there is an additional resistance to any fluoroquinolone and any second-line injectable treatment, and it requires lengthy use of more toxic antibiotics such as meropenem, imipenem-cilastatin, macrolides, with a yet unknown and unclear efficacy (26).

All in all, drug resistance, adverse effects, poor drug quality, malabsorption or underdosing, nonadherence represent undeniable causes for treatment failure, increasing the need to investigate biomarkers that are conclusive for predicting relapses after treatment (3, 13). Moreover, the only available antitubercular vaccine does not imply protection against adult lung active TB, the most prevalent form, so there is a rush all over the world to determine new antituberculotic mechanisms, drugs and vaccines, in order to eradicate this ancient disease (17, 23).

New anti-TB drugs and regimens

New active substances such as *bedaquiline and delamanid*, both discovered in 2013, were subjects in trials for usage in MDR-TB and have received conditional approval based on Phase IIb trial results, as WHO underscores (3,12,13,17). Actually, delamanid, an imidazooxazole derivative, was found to accelerate sputum clearance of *M. tuberculosis* by almost 50% in 2 months, by liberating toxic nitric oxide within macrophages (3). Since 2014, WHO has recommended the use of delamanid as part of antitubercular regimen in MDR-TB patients, including children aged 6-17 years, due to its safety and efficacy (13). Bedaquiline (BDQ), a diarylquinoline, is the only clinical drug approved in the last 40 years and has also a molecular mechanism by directly blocking the adenosine triphosphate synthase complex, but unfortunately, it involved higher death rates in patients, even though the treatment provided efficacy (3, 13, 22). BDQ has shown activity against non-replicating and hypoxic populations of *Mycobacterium*, a first bacteriostatic effect followed by a bactericidal effect after only 4 days of treatment which means it is possible that BDQ has additional targets unidentified yet (22, 27). Different all-oral regimens containing BDQ and delamanid for MDR-TB are involved in a global clinical development organized by WHO in 2018, which tries to combine old tuberculostatic agents with new ones, such as: BDQ-pretomanid-moxifloxacin-pyrazinamide regimen, delamanid-linezolid-levofloxacin-pyrazinamide for quinolone sensitive MDR-TB, BDQ-pretomanid-linezolid, BDQ with two optimized background regimens oral for 9 months or with oral and injectables for 6 months called the STREAM (Standardized Treatment Regimen of Anti-TB Drugs for patients with MDR-TB) trial (13, 26, 27). The STREAM trial was initiated in March 2016 and the first results are expected not

earlier than 2020, but WHO mentions different trials involving BDQ as treatment in children TB, implemented in Russia, South Africa and in the Philippines (13, 28). The mediocre outcomes in MDR-TB treatment success rates have led to a series of cohort studies over 12 years in Bangladesh, and, for example, the last cohort had a cure-rate of 87.9% using a 9-months fluoroquinolone-regimen (gatifloxacin and isoniazid given at a higher dosage) in 206 patients (28). The purpose of STREAM trial, stage 1 in Ethiopia, South Africa, Vietnam and Mongolia, is to compare the 9-month Bangladesh-regimen with a standard WHO-recommended care comprised of moxifloxacin, clofazimine, ethambutol and pyrazinamide given for 40 weeks with kanamycin, isoniazid and prothionamide given during the 4-month in the intensive phase (13, 28). In stage 2 of STREAM trial, BDQ replaces kanamycin over 9 months, and levofloxacin replaces moxifloxacin, in order to avoid cardiovascular adverse effects, but results have not been published yet (13, 28, 29). The last anti-TB drugs, mentioned by WHO, involved in phases I of clinical trials are TBA-7371, shown to be effective against resistant M. tuberculosis strains, in the USA and TBI-166, with a similar efficacy to clofazimine, in China (13, 28).

Repurposing of existing drugs

Development of new TB treatments or new antibiotics is time consuming and requires high financial resources, so the repurposing of already existing drugs represents an actual possible shortcut (30, 31). This matter would not only reduce the duration of curative treatment for TB, but the initiation of host-directed therapies would enhance the effects of standard treatment and would decrease the relapses or the number of patients with MDR-TB (30,32).

The first study on the potential effect of *statins*–3-hydroxy-3-methyl-glutaryl-CoA reductase or HMG-CoA reductase inhibitors- was performed 19 years ago when Montero *et al*. showed that fluvastatin could strengthen the host response against *M. tuberculosis* by releasing more cytokines and promoting the activation of immune responses (31, 33). Furthermore, statins increase the number of interleukins through a pleiotropic- immunomodulatory and anti-inflammatory- effect on the whole immune system, they limit the mycobacterial growth by promoting autophagy and apoptosis in macrophages and by inhibiting the synthesis of cholesterol, due to their label as lipid-lowering drugs (31, 33, 34). *M. tuberculosis* needs lipids and cholesterol as a carbon source to develop its virulence factors and its cell wall, to internalize itself in host cells, to lower its susceptibility to antibiotics, which explains why hypercholesterolemic mice infected with *M. tuberculosis* have an accentuated pulmonary pathology (33, 35). The composition in lipids of the bacillus wall determines permeability to other substances and most important, its resistance to antibiotics through its architecture formed by peptidoglycan, arabinogalactan and mycolic acids linked with those lipids (30, 32, 35). Therefore, statins augment protection against TB by lowering the infection-induced lipid accumulation in macrophages, reduce the reactivation of latent TB, attenuate cholesterol levels, prevent the lung tissue destruction, regardless of sex, age and comorbidities (36). Interactions between standard antituberculotic agents and statins have also been studied and the addition of 25 mg/kg simvastatin to rifampicin 10 mg/kg, isoniazid 10 mg/kg and

pyrazinamide 150 mg/kg given five times per week, showed an important reduction in bacillary populations even in the 56th day of treatment (30). Other studies showed that the association between rifampin and atorvastatin did not increase muscle tissue damage, nor the hepatotoxicity, even though statins have been described as generators of oxidative stress in hepatic cells (32). Yet, simvastatin shortens the 6 months antituberculotic treatment, but triggers myopathy and rhabdomyolysis faster than atorvastatin and pravastatin, which are safer to use because they have not shown interactions with rifampicin (32, 34). The statins mechanism, as inhibitors of HMG-CoA reductase, leads to new ideas due to the fact that the enzymatic inhibition down-regulates not only the biosynthesis of cholesterol, but also of lipid hormones, isoprenoids and vitamin D (18, 31).

In the last 5 years, studies have shown that *vitamin D* is involved in innate immune responses, in host defense, in the control of proliferation and necroptosis of M. macrophages (19, 21). Vitamin D treatment increases not only protein kinases leading to inhibition of proinflammatory cytokine production in monocytes and macrophages, but also calcium absorption which can activate autophagy through other kinases and phosphatases and compromise the bacillus viability (2, 21). Since ancient times, TB tends to occur during the colder season when cutaneous synthesis of vitamin D from the sun exposure is reduced and serum levels are lower, and maybe treating TB patients before the 17th century by exposing them to sun and fresh air was not a bad idea after all (17, 21). Deficiencies of vitamin D and vitamin A -lipophilic vitamins- and polymorphisms in vitamin D receptors have been associated with TB risks, because there is considerable evidence that vitamin D is essential for human macrophages to kill *M. tuberculosis* in vitro (3, 13). Patients supplemented with 0.25 mg daily of vitamin D reduced the time for sputum smear conversion from positive to negative, but while other studies have proven to be disappointing, vitamin D supplementation seems to protect against infection with *M. tuberculosis* (21, 24, 25). The antimycobacterial action of statins may be a faster and more efficient way to provide an entirely new class of drugs to treat TB and may also be a very important association with the standard regimen against MDR-TB or even XDR-TB (32). Additional preclinical studies for both statins and vitamin D are required to identify further possible interactions, the safest dosage and the optimal way to administer, as prophylaxis or not (19, 31).

Another surprisingly available class of nonantibiotic drugs, discovered since 1883, has shown antituberculotic activity for more than decades, but has only been intensively studied in the past years (37,38). What is special about *phenothiazines* is that they can suffer core structure modifications in a possible manner, by remodeling N-alkylamine side chains with N-alkylsulphonates, that does not affect their ability to inhibit *M. tuberculosis*, but only their ability to influence the nervous system activity (37). Non-neuroleptic phenothiazines down-regulate calcium and potassium intracellular transport as calmodulin inhibitors, promote acidification of the phagocytic cells, therefore stimulating macrophages to kill the bacillus (37, 38). Thioridazine, especially in its (-) enantiomer form with no central nervous activity and no cardiac side effects, is able to inhibit the efflux pump in *M. tuberculosis*, to

modify the transport of various substances through the membrane, to increase the susceptibility to fluoroquinolones and to reduce resistance to isoniazid (38, 39). A promising cure in Argentina, of 10 patients from 12, with MDR-TB and XDR-TB, generated by the association of 75 mg of thioridazine with linezolid and moxifloxacin, makes phenothiazines suitable potential candidates for MDR-TB treatments (38, 40). Another study determined a human dosage of 25 mg/kg of thioridazine, associated with isoniazid and rifampicin, to be well-tolerated and to have antimycobacterial therapeutic efficacy and it also appeared that thioridazine targeted both replicating and nonreplicating bacilli in the murine model of TB (41). Furthermore, although thioridazine was ineffective as single antituberculotic therapy, in coadministration with isoniazid, it prevented the selection of resistant strains, through different pathways, mainly because it blocked the calcium binding to vital mycobacterial proteins and produced cell wall damage (39,40). They are not only antimycobacterial, antibacterial or antifungal, but also antihistaminic, analgesic, antimalarial, antiviral, anticancer and anti-inflammatory, phenothiazines being capable of activating biological systems, interaction with cellular DNA, influence over cellular neurotransmitters with a lipophilic character, so chlorpromazine, methdilazine, thioridazine and trifluoperazine are worthy of further investigations in latent TB, MDR-TB and XDR-TB cases (38, 39, 41).

CONCLUSIONS

Our study highlighted that the patient's immune status and social condition represent important factors which influence the susceptibility to infection with *M. tuberculosis* and the TB severity, one of the world's leading causes of death. In order to eradicate a bacilli that has a greater life experience than the worldwide human population it is important to gather all information regarding old and standard treatments, to repurpose drugs to reduce costs, to grow efficacy of antituberculotic agents, to define biomarkers and to understand the local survival mechanisms of the internal mycobacterial cells. For every molecule our body uses to escape from infection, Mycobacteria fights back with more molecules, so further biochemical studies should investigate not only the patient's status, but also the "social condition" of *Mycobacterium tuberculosis*.

CONFLICT OF INTERESTS

There are no conflicts of interest. All authors made equal contribution to the paper, to that of first authors, and thus share main authorship.

SOME CARDIOVASCULAR EFFECTS OF ALCOHOL. PROSPECTIVE STUDY ON 200 PATIENTS BETWEEN 2006-2008 (Abstract) : Several studies have confirmed that drinking a moderate amount of alcohol (ethanol) decreases the risk of heart disease, heart attack, and stroke. There are several mechanisms of health benefits of alcohol, which include anti-inflammatory, antioxidant and anti-blood clotting effects. The aim of the study is to underline the effects of alcohol consumption over cholesterol blood levels. **Material and methods** : The study was conducted on 200 individuals from urban and rural areas of Iaşi county (100 being alcohol consumers), during the 2006-2008. **Results** : The cholesterol blood levels are greater than the normal accepted values, both in men and women (urban and rural), drinkers or non-drinkers. **Conclusion** : The cholesterol levels are higher in drinkers, women and rural population included in our study. We did not do a quantification of other factors which may increase the cholesterol blood levels, such as diet, body mass index and physical activities. **Key words** : DRINKERS, ALCOHOL BENEFITS, CHOLESTEROL BLOOD LEVELS

NEUTROPHIL-LYMPHOCYTE RATIO IN DIFFERENTIAL DIAGNOSIS BETWEEN TUBERCULOSIS AND MALIGNANT PLEURAL EFFUSIONS

NEUTROPHIL-LYMPHOCYTE RATIO IN DIFFERENTIAL DIAGNOSIS BETWEEN TUBERCULOSIS AND MALIGNANT PLEURAL EFFUSIONS (Abstract): Pleural effusion (PE) is a common clinical problem, etiologically, difficult to diagnose, requiring invasive procedures. During last years, serum neutrophil-lymphocyte ratio (NLR) has been investigated as a new inflammatory marker. The **aim** was to evaluate serum NLR in differential diagnosis between tuberculous (TB) and malignant pleural effusions (MPEs). **Material and methods**. A retrospective study included adults, diagnosed with PE and hospitalized in Constanta Pulmonology Clinic, between March 2017 and September 2018. Biomarkers were collected from serum and pleural fluid. Final diagnosis of malignancy was assessed by pleural fluid cytology and/or pleural biopsy. The evidence of Mycobacterium tuberculosis in smears or culture from pleural fluid or caseous granulomatous specific lesions in pleural biopsy samples were considered suggestive for TB etiology. **Results:** 463 cases were divided into 110 MPEs and 353 TBPEs. NLR increased in both categories of patients, mainly in malignancy group (p=0.001). **Conclusions:** serum NLR seems to be useful in evaluating the etiology of malignant or TB pleural effusions. **Keywords:** PLEURAL EFFUSIONS, TUBERCULOSIS, CANCER, NEUTROPHIL-LYMPHOYTE RATIO.

Pleural effusion (PE) is a frequent chest disease, with difficult etiologic diagnosis, requiring invasive procedures (1). In Romania, tuberculosis (TB) and malignancy are the most common causes of exudative PEs (2). Detection of *Mycobacterium tuberculosis* in pleural fluid has low sensitivity due to paucibacillary nature of TB. The evidence of caseous granuloma in pleural samples, obtained by invasive procedure like pleural biopsy, is representing gold standard of TBPE diagnosis (2, 3).

Malignant pleural effusions (MPEs) are diagnosed by revealing tumor cells in pleural fluid or tissue, by biopsy. Both malignant pleural mesothelioma and paraneoplastic effusions represent advanced forms of cancer, sometimes difficult to differentiate (4-7). Analysis of pleural lactate dehydrogenase (LDH), proteins, glucose, adenosine deaminase enzyme level (ADA), and differential cell counts in pleural fluid, remains essential and challenging for PEs etiological diagnosis (2). While neutrophilic predominance in pleural fluid is a predictor for parapneumonic effusion and elevated pleural ADA for TB (2), there is no specific biomarker for MPEs. During last years, neutrophil-lymphocyte ratio (NLR) has been investigated in serum as a new inflammatory marker, associated with poor survival in many types of solid tumors, MPEs including mesothelioma (1, 3, 8) and predictive for bacteremia, discriminating TB from parapneumonic effusions (8-10). NLR is, also, correlated with worse prognosis of inflammatory or infectious diseases, including tuberculosis and pneumoconiosis (11-13). Chest precision medicine is constantly searching for genetic, epigenetic, metabolic, inflammatory, oxidative stress biomarkers (14) and more affordable biomarkers as blood eosinophils (15), serum aminotransferases (16, 17) or blood NRL in COPD patients were proposed (18).

The purpose of this study was to evaluate the utility of NLR in serum, for exudative PEs differential diagnosis between TB and malignancy.

MATERIAL AND METHODS

A retrospective study included 463 adults, hospitalized, in Constanta Pulmonology Clinic between March 2017 and September 2018, for exudative PE. Patients informed consent the procedures for PE investigation. Study was approved by the Ethics Committee of Constanta Clinical Pulmonology Hospital, Romania, and conducted in accordance with the principles of Helsinki Declaration. Serum and pleural fluid biomarkers, such as LDH, C-reactive protein (CRP), protein, glucose, ADA, differential cell counts were assessed. Patients with transudative effusions were excluded. Etiology was based on pleural fluid cytology and bacteriology, as well as histological exam of pleural biopsy samples. All cases were divided into two groups: TBPEs and MPEs. NLR score was obtained by dividing the absolute neutrophil count by the absolute lymphocyte count in the complete blood count of the serum. Statistical analysis, performed by SPSS software version 25.0, used Pearson or Spearman correlation coefficient to evaluate the linear respectively non-linear correlation between quantitative variables or categorical variables. Univariate comparisons were made with χ^2, 2-sample t-tests, Mann-Whitney test. The difference was considered significant when $p < 0.05$.

RESULTS

463 cases with exudative PEs, mainly older in MPE group (66.64 +/- 11.40 versus 45.10 +/- 18.17; p=0.000), were divided into 2 groups: TB (n=353) and MPEs (n=110) (Table I). Statistically significant differences between groups were found for white blood cells (WBC) counts (p=0.003), pleural proteins (p=0.000) and ADA (p=0.000). Because both variables had not a normal distribution, Mann Whitney U Test was applied revealing significant differences for blood NLR (p= 0.0001) and pleural LDH values (p=0.0004) among groups (tab. I). Distribution of cases by

etiology, according to NLR quartiles (q1 < 2.3; q2= 2.3-4.95; q3 > 4.95), was statistically significant (p=0.0003) (fig. 1).

Overall, both average and median values of NLR were higher in men (4.60; 3.5) versus women (4.01; 2.95) (p=0.003), especially among MPE cases (p=0.009). Significant correlations between NLR and WBC, hemoglobin, pleural LDH were found in both groups (tab. II). NLR correlated with hemoglobin (p=0.000) and pleural LDH in TB group (p=0.027). Univariate analysis showed high NLR (≥ 5), low serum albumin (<3 g/dL), high neutrophil count (≥8,000/mm^3), and low lymphocyte count (<1,000/mm^3) associated with cavitary pulmonary TB. Multivariate analysis showed that high NLR and low serum albumin were associated, also, with cavitary form of pulmonary TB.

TABLE I

Characteristics of patients with pleural effusions (PEs)

Variable	Tuberculosis PEs (n=353)	Malignant PEs (n=110)	Total (n=463)	p value
Age	45.10 (±18.17)	66.64 (±11.40)	57.24 (±18.19)	p= 0.000

DISCUSSION

In the last decade, NLR was proposed as a biomarker of prognosis of COPD (18), benign or malignant solid tumors (8, 19), occupational disorders (13, 20). Smoking, occupational and environmental exposure to air pollutants or known carcinogens may contribute to increased prevalence of lung cancer (21-25). PE can be the first manifestation of severe disorders, including TB and cancer. Mortality rate caused by lung cancer is high in Romania (26). Templeton *et al.*, in a recent meta-analysis of 100 studies comprising 40,559 patients with solid tumors, have found a consistent effect of elevated NLR on survival, among various disease subgroups and across cancer stages (8). The aim of this paper was to evaluate if NLR could be useful in the differential diagnosis between TB and MPEs. In our study, serum NLR had significant higher mean and median values (4.94; 3.8) in MPEs versus TB (4.40; 3.1) (p= 0.0001). NLR values range from 0.78 to 3.53 in healthy adults and cut-off value for mortality in specific diseases is between 3 and 5 (11, 19). There is a controversy on the optimal NLR cut-off values. Can NLR be an indicator of MPE as in malign nodular thyroid disease? Our study revealed high mean value (4.94) suggestive for worse prognosis. Peripheral blood lymphopenia in cancer represents a predictor of poor survival in advanced stages of cancer (27, 28). The impact of tumor growth on the host immune response is revealed by elevated NLR but cut-off is on debate (7, 29). Elevated blood NLR associates with

decreased lymphocytes and increased neutrophils, suggesting systemic inflammation and impaired cell-mediated immunity, and systemic inflammation and could be an important promoter of cancer-related cachexia (27). Inflammation plays an important role in different stages of tumor genesis (8) but the mechanisms associated with elevated NLR and poor outcomes in cancer remain unclear. TB patient identification at high risk of severe forms or evolution, reactivation or early death can be predicted by NLR (30). TB is still considered one of the oldest infectious diseases and a major cause of morbidity and mortality worldwide, and in Romania (31). High NLR may reflect relative lymphopenia. Immunosuppression related to HIV infection, biological treatments or associated comorbidities are main causes of TB infection progression to disease (32-37). Few data were published about NRL in TBPEs (1, 3). Nakao and al. reported elevated NLR in association with pulmonary cavitation (38) as our study revealed.

CONCLUSIONS

NLR is a composite marker which reflects the effects of the adaptive and innate immune responses in tuberculosis and malignant pleurisy. Because neutrophil and lymphocyte counts are nonspecific parameters, NLR seems to be a potential biomarker for differential diagnosis of TB and MPEs, but the appropriate cut-off should be further investigated.

RISK FACTORS ASSOCIATED WITH RECURRENCE OF CLOSTRIDIOIDES DIFFICILE INFECTION (Abstract): **Aim** To evaluate the impact of selected risk factors (social, demographic, habitual, comorbidities) on the relapses in the infection with *Clostridioides difficile*. **Material and methods:** A retrospective analysis of the hospital - based medical records of the patients with *Clostridioides difficile* infection (CDI) admitted in the Clinical Hospital of Infectious Diseases Iasi, Romania during 2017. **Results:** We retrospectively evaluated the medical data of patients with CDI admitted in the Clinical Hospital of Infectious Diseases "Sf. Parascheva" Iasi, Romania and included in our study 82 patients that had history of at least one episode of CDI. Risk factors that could be associated with young patients (under 40 years) were malnutrition. Alcohol - related liver diseases and tuberculosis were the most prominent risk factors in patients aged 40-60 years. Patients aged between 61-80 years, frequently associating chronic diseases were the most affected. **Conclusions:** Elder patients are representing an exposed group and have increased vulnerability to infection with *Clostridioides difficile*, and because of that they require a special interest for antibiotic stewardship. **Keywords**: CLOSTRIDIOIDES DIFFICILE, ELDERLY, ABUSE, RISK FACTORS, RECURRENCES.

Infectious diseases are a common cause of increased morbidity and mortality in elderly. Many factors (e.g. conditions, diseases or exposures) which increase the risk for infections may be found in older patients. The decline in immune function as result of the physiological process of immune senescence in addition to other pathological host factors (e.g. comorbidities, polypharmacy, frailty/impaired cognition, immobility) is one of the most frequent cause of the increased vulnerability of elderly to infections. (1)However, many other social factors may be involved. Some of these factors are poor understanding or acceptance of prevention, psychosocial isolation, depression, malnutrition. Among infectious diseases, *Clostridioides difficile* (formerly *Clostridium difficile)* infection (CDI) is of special interest since it is the most common infection with medical and pharmacoeconomic impact.

First identified in 1935, *Clostridium difficile* is an anaerobic Gram-positive, spore

forming rod, phylogenetically distant from the rRNA clostridial main cluster. Recently it was redefined as *Clostridioides difficile (C. difficile).* The pathogen emerged as an important pathogen in the late 1970s and currently is considered the main pathogen of healthcare-associated infectious diseases (2). Two virulent *C. difficile* strains ribotypes RT 027 and RT 078 were identified. Ribotype RT 027 has become the most important hypervirulent strain responsible for severe infections and increased mortality (3).The most important risk factors for developing CDI are antimicrobial treatment (mainly 3rd generation cephalosporins, penicillins, fluoroquinolones, lincosamines) and age. Advanced age is a noted risk factor for CDI, and commonly associated with mortality in developed countries (1). Among risk factors specific to elderly are the age-related changes in physiology, including immunosenescence and changes to the gut microbiome. Additional risk factors specific for this infection include immunodeficiency, chemotherapy, organ transplantation, inflammatory bowel disease, chronic kidney disease and exposure to individuals with *C. difficile* (3).The most difficult and increasingly common challenges in the management of CDI is the recurrent infection. Age > 65 years, severe underlying disease and continued use of antibiotics for non- CDI are considered the most preeminent risk factors for recurrences(4). The objective of this study was to examine the relationships among selected risk factors (social, demographic, habitual, comorbidities) on the recurrences of the CDI.

MATERIAL AND METHODS

This was a retrospective analysis of the hospital-based medical records of the patients with CDI admitted in the Clinic of Infectious Diseases Iaşi during 2017. *C. difficile* infection was defined by the presence of diarrhea and a positive *C. difficile* cytotoxin (toxin A and toxin B) chromatographic immunoassay. Diarrhea was defined as more than 3 loose, but also watery or unformed stools per day. The infection was classified as community-associated if the *C. difficile*-positive specimen was obtained in an outpatient without any risk factors or within 3 days after hospital admission. All other cases were considered healthcare- associated infections. Recurrence was defined as a second episode of CDI within 60 days after the first episode. We included in our analysis only cases of at least one recurrence of CDI. Patients with diarrhea and negative result for *C. difficile* toxins were excluded. The following data were collected: demographic data, social (e.g. presentation from home versus nursing facility, including nursing homes/ long-term care facilities; family caregivers) and/or habitual conditions (e.g. malnutrition, alcohol consumption).

Medical (co-morbidities-diabetes mellitus, malignancy, kidney disease, hypertension, coronary artery disease, neurological and psychiatric disorders) and medication (e.g. antibiotic use in the previous 3 months, proton pump inhibitors) were recorded and Charlson comorbidities index was used to represent the cumulative burden of comorbid illnesses (6). Results of blood tests and stool sample tests were evaluated. Age, area of provenience (rural versus urban), comorbidities, social and habitual characteristics were considered risk factors for CDI recurrences.

Results were analyzed with descriptive statistics. The relationship between risk factors and disease evolution was evaluated

using Spearman correlation test. Univariate analysis was performed using the χ^2 test to assess the differences between different age groups. Two-sided significance was assessed for all variables, applying a cut-off value of $p < 0.05$.

Statistical analysis was performed using XLSTAT version 2018 software (*Addinsoft Co*, USA). The study was approved by the Ethics Committee of the Clinic of Infectious Diseases, Iasi.

RESULTS

From a total of 247 patients with CDI hospitalized during 2017in our hospital, 82 patients had between 1 and 6 episodes of recurrences. Patients from rural areas (47.56% cases) had a higher average age (62.45 years) compared to urban ones (52.44% cases) with a mean age of 52.6 years. Some of elderly patients presented from a nursing facility; however, more than 60% of patients presented from home, but the majority of them had a history of hospitalization in the previous months. Most of the patients were aged between 71-80 years old, but the range was wide (15-88 years) (fig. 1).

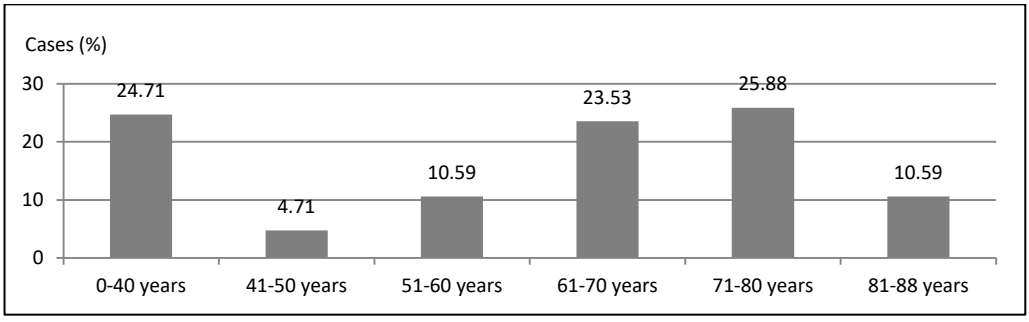

Fig. 1. Patients' age distribution

There were not significant differences gender- related; however, a slight increased incidence in females was noted (53% versus 45.79% cases) (tab. I).

TABLE I

Patients' characteristics

Age	Male (%)	Female(%)	Rural (%)	Urban (%)	Charlson comorbidity index	Mean duration of hospitalization (days)
0-40 years	42.86	57.14	42.86	57.14	1.04	9.83
41-50 years	25	75	25	75	1.36	11.27
51-60 years	22.22	77.78	55.56	44.44	3.2	12.5
61-70 years	65	35	40	60	4.68	11.23
71-80 years	40.9	59.1	54.54	45.46	5.39	10.16
81-88 years	33.33	66.67	44.44	55.56	7.1	12.63

An age-group analysis of impact of risk factors on CDI recurrences showed no significant differences between groups, except for young patients (aged below 40 years) (p=0.034). The most important underlying conditions in patients aged below 50 years were associated with a poor social status (28.57% cases). Alcohol -related liver diseases (over 50% cases) and tuberculosis (25% cases) were the most prominent risk factors in patients aged 40-60 years. In older patients, recurrence of infection was noted especially in cases of malignancies – related immunosuppression (20% cases). Malnourished patients aged between 61-80years, frequently associating chronic diseases (diabetes, malignancies, but mainly with cognitive impairment) were the most affected (fig. 2). The small sample size of patients aged over 80 years could not offer a good estimation. In 20.73% cases of the entire studied group, patients had previous antibiotherapy.

The variance analysis showed a good correlation between risk factor and age in elderly compared to young patients (fig. 3). We expected this result since the Charlson index increased by age.

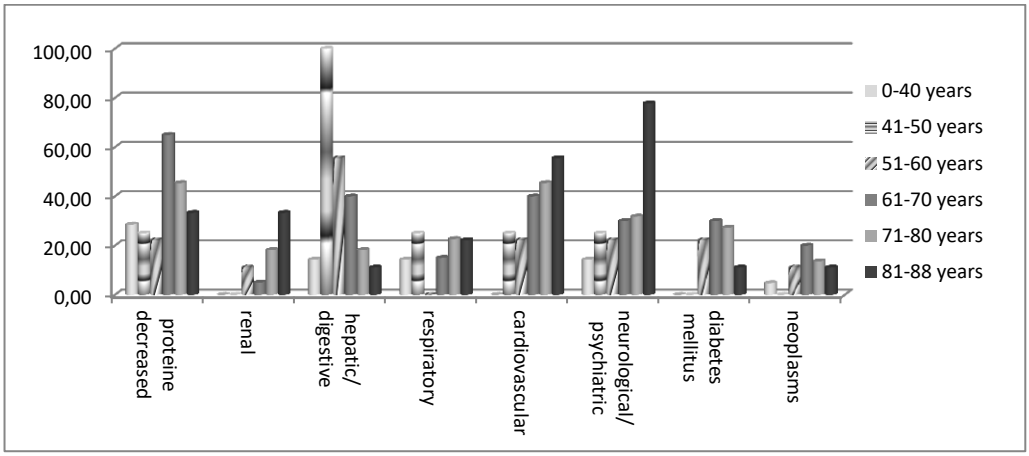

Fig. 2. Co-morbidities incidence by age groups

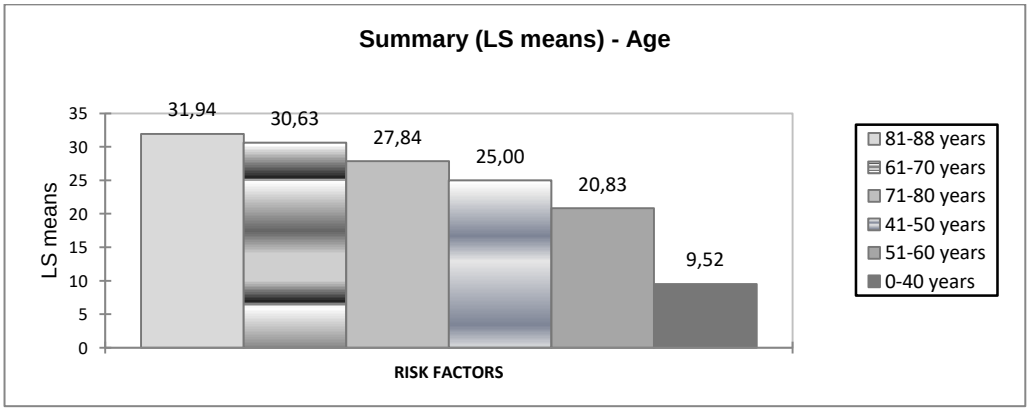

Fig. 3. Correlation between age and risk factors

Spearman correlation test identified renal diseases (renal failure, urinary catheterization) (coefficient Spearman = 0.928) and neurological and psychiatric diseases (tetraplegia /paraplegia, cognitive impairment) (coefficient Spearman = 0.943) as risk factors for CDI recurrences (tab. II).

TABLE II
Spearman correlation test results

Variables / Age	Protein decreased	Renal	Hepatic/ digestive	Respiratory	Cardio- vascular	Neurological	Diabetes melli- tus	Neoplasm
Correlation matrix (Spearman)	0.543	0.928	-0.429	0.257	0.943	0.943	0.580	0.638
Confidence intervals (95%)	[-0.540 , 0.949]	[0.280 , 0.995]	[-0.928 , 0.620]	[-0.710 , 0.888]	[0.383 , 0.996]	[0.383 , 0.996]	[-0.509, 0.955]	[-0.452, 0.964]

DISCUSSION

Clostridioides difficile has become the most common cause of health care–associated infections worldwide, and recurrence rates for CDI have been reported to vary from 5% to 50%, with an average of 20% (7). Mortality rate associated with CDI has been found to range between 5% - 34% and is doubled in intensive care unit patients (8, 9). Most of the CDI are associated with health care exposure (in hospital or even nursing home stay), but recent studies revealed that incidence of community-acquired CDI significantly increased up to 30% in recent years. In our studied cohort, up to 30% patients had CDI recurrences, as noted before in other studies (10, 11). Patients from urban areas, as well as those from rural areas, were similarly exposed to risk factors for recurrences of CDI. Our study confirms the finding in other studies that older age is a risk factor for CDI recurrences since the highest incidence was found in patients over 65 years. For every additional year of age after age 18, the risk of health care - associated CDI increased by approximately 2%; thereby, age > 65 years increases the risk for CDI 5 to 10-fold (12, 13). Significant risk factors for health care- associated CDI noted in other studies and also found in our analysis were use of antibiotics, and use of proton-pump inhibitors, chemotherapy, and hospitalization in the previous 2 months (12).As noted in previous studies, malnutrition and alcoholic and non-alcoholic cirrhosis were risk factors for CDI irrespective of age, possible due to immunosuppression induced by these conditions (14, 15). In addition, tuberculosis was found the main risk factor for recurrent CDI in 6% cases of our cohort, but tuberculosis was also identified as an independent risk factor for CDI mortality (16). Overall, patient over 65 years old, with multiple chronic disorders, functional incapacity, physical disability and

cognitive impairment were the most vulnerable for CDI recurrences. Patients with cognitive impairment and dementia are of special interest, since even with adequate food intake, these patients associate malnutrition responsible with a four - fold increase in infections (17). For elderly coming from long-term care facilities or nursing homes, not only host factors or antibiotic consumption were responsible for CDI. The primary infection and its recurrences are often facilitated by transmission of the pathogen within a closed environment, adding sometimes certain neuro-and locomotive disabilities and inability to ensure a decent living (18).

On the other hand, community-residing elderly with moderate to severe dependency and family caregivers represents a special situation (19). Elder abuse is defined a mistreatment that includes physical, sexual, psychological, emotional and financial abuse, and neglect, and violates the human rights (20). This type of abuse has significant negative impact on the quality of life with deterioration of the health status. Unfortunately, this situation is also frequent in our country. Even we could collect limited data about caregivers in our study, we have noticed that older patients with physical inability and mental impairment were often neglected, requiring prolonged hospitalization and even psychological assistance (21).

As a line of research, it could be interesting to see the role NADPH- oxidizes, that was originally identified as a component of innate host defense and is involved in many key biological function(22).

CONCLUSIONS

Older patients with risk of life-threatening infections, including *Clostridioides difficile*, require a special interest for antibiotic stewardship to reduce morbidity and mortality. In addition, since mistreatment may have serious effects on elderly's health, preventive measures must be put into place to combat neglect of caregivers against older people.

CARDIOPULMONARY RESUSCITATION - COULD BE INAPPROPRIATE ? THE EMERGENCY MEDICINE PROFESSIONALS PERCEPTION IN NORTH-EAST ROMANIA (Abstract): Cardiopulmonary resuscitation (CPR) is started irrespective of comorbidity or cause of cardiac arrest. We aimed to determine the prevalence of perception of inappropriate CPR of the personnel from Emergency Department (ED), the factors associated with perception and the relation to patient characteristics. **Material and methods:** A survey based on questionnaire was conducted in an ED of University Hospital, as a part of multicentric European study. Factors associated with perception of CPR and outcome were analyzed on statistic base. **Results:** Of the 54 participating clinicians, 57.4% perceived their last CPR attempt as appropriate, 38.9 % were uncertain about its appropriateness and 3.7% perceived inappropriateness. The prevalence of perception of inappropriate CPR was higher when one of this factor was present: non-shockable initial rhythm, inappropriate quality of CPR performed by witnesses before arrival, the advanced age of the patient, terminal neoplasia, low quality of life before cardiac arrest. The ED staff needs an early recognition of CPR futility, feedback, training and teamwork and performance evaluation after each CPR attempt. **Conclusions:** The perception of inappropriate CPR is present in a small percent inside ED staff. Factoring clinical judgment into the decision to (not) attempt CPR may reduce harm inflicted by excessive resuscitation attempts. **Keywords:** CPR, ED PERSONNEL, INAPPROPRIATE, SURVEY.

Cardiopulmonary resuscitation (CPR) was introduced in 60's to reverse the cardiac arrest of patients with reversible conditions such as acute myocardial infarction within the first minutes after collapse (1). Currently, most cardiac arrest patients receive CPR irrespective of their functional status and comorbidity, cause of the arrest and delay after the collapse (2, 3). Some studies have shown that over time neurologically favorable outcome after CPR has improved, but this improvement is lower for cardiac arrests with an initial non-shockable rhythm compared to an initial shockable rhythm. Data from the Cardiac Arrest Registry to Enhance Survival (CARES) from 2005 until 2012 show an increased adjusted rate of survival to hospital discharge from 2.1 to 3.9% for non-shockable rhythms and from 16.1 to 21.1% for shockable rhythms (4). A nationwide Japanese registry from 2005 until 2014 reports an increase of 1-month survival with

favorable neurological outcome from 0.8 to 1.2% for bystander-witnessed non-shockable arrests and from 10.1 to 24.9% for bystander-witnessed shockable arrests (5).

Inappropriate CPR attempts are undesirable from both the medical personnel and the scientific perspective. The patients suffering a cardiac arrest are particularly susceptible to loss of dignity and to suffer dehumanization, because they lack many typical attributes of modern human beings such as consciousness and self-determination. Furthermore, patients who are successfully resuscitated have residual cognitive and physical deficits and never recover, thus prolonging their vulnerability to disrespect, often with profound negative consequences for their relatives (10). From the logistic and financial health perspective, undifferentiated application of cardiopulmonary resuscitation may unbalance the appropriate allocation of resources.

Previous studies by Marco *et al*. found in 1995, and again in 2007, that 55% and 57% of surveyed emergency physicians, respectively, reported having attempted more than ten resuscitations that were perceived as futile in the prior three years (8). A survey found that emergency medical technicians estimated 50% of resuscitation attempts to be futile, defined as an exceptionally low likelihood of success (9). Studying clinician perceptions of inappropriate care is important since they have been associated with moral distress (11, 12) and burnout (13), which are related to self-reported suboptimal patient care practices (14, 15). The quality of future resuscitation attempts may be negatively affected if medical professionals perceive CPR attempts as inappropriate and resulting in a poor outcome.

No studies in Central and East European countries related the ED team perception of inappropriateness of CPR to actual patient outcomes. The objective of this study was to determine the prevalence of the uncertainty about CPR appropriateness and of the perception of inappropriate CPR in prehospital and emergency departments and the association with survival to hospital discharge. The secondary objectives ware to assess the association between patient and situation related factors, personnel characteristics, organizational and work-related factors, the perception of inappropriate CPR and return of spontaneous circulation (ROSC).

MATERIAL AND METHODS

This Romanian study is a part of an international multi-center cross-sectional survey conducted in 288 centers in 24 countries, the REAPPROPRIATE study, coordinate by Belgium (1). The study population consisted of ED personnel from "Sf. Spiridon" County Clinical Emergency Hospital from Iasi who are directly involved in the management of cardiac arrest in the emergency department or the prehospital setting. The data collection period was from March until November 2015 and a modified Delphi method was used to adjust a questionnaire. First version of the questionnaire was prepared by a multidisciplinary expert panel: two emergency physicians, two intensivists, two emergency nurses, one geriatrician and two clinical psychologists from Netherlands. This Dutch version had an adaptation and translation into English and after the questionnaire was translated into Romanian followed by re-translation, necessary to achieve cultural and functional equivalence (16). We designed the survey based on the questionnaire, using a 4-point rating scale, similar with Likert scale from "Fully

agree" to "Fully disagree". ED personnel, physicians and nurses, were asked about their demographic and professional background and ED working environment. Also they were asked to recall the latest cardiac arrest they encountered and to answer if they "fully agreed with starting the resuscitation" (own perception of appropriate CPR), "were unsure resuscitation should have been started" (uncertain about CPR appropriateness) or "were sure resuscitation should not have been started" (inappropriate CPR). Subsequently questions were about details of the resuscitation circumstances such as: site of arrest, patient age, gender, initial arrest rhythm, presence of a witness, ROSC, personal impression of the patient's physical condition, probable cause of arrest. All the data was included in a statistical analysis using *SPSS 25.0***.** This study was conducted in accordance with the Declaration of Helsinki. Because informed consent was not required, the study was approved by the Ethical Committee of "Grigore T. Popa" University of Medicine and Pharmacy from Iasi.

RESULTS

We sent 58 questionnaire and we received 54 completed. The latest CPR attempt encountered was reported by 54 physicians and nurses. The average age of the participants was 31+/-7.192 years, with a maximum of 53 and a minimum of 22 years. The distribution by gender was: 68.5% women and 31.5% males, similar with the gender structure inside the health system in Romania. Of the entire group, 51.8% were training doctors, 18.4% were Emergency consultants and 29.8% nurses. According to the activity field: 87% were directly involved in emergency medicine inside ED and 13% were indirect involved in emergency medicine, being radiologist. The number of working hours / week: average 40 with the limits between 30 (1.7%) to 78 (1.7%)

Years of the experience in the ED inside the population group were less than 1 year-14,8%, 1-5 years (29,7%), between 5-20 years- 53.6% and up to 25 years (1.9%).

74.1% admitted to have religious beliefs, 18.5% showed no religious beliefs while 7.4% would not answer. There is no correlation between religion and the initiation of resuscitation maneuvers or their uselessness.

Only 6.9% of respondents are involved in teaching ALS and BLS courses. The hours of BLS training attended in the last 12 months varies between 0 (for 50% of the respondents) and 48 hours (for the 5.2% of respondents).

The number of ALS course hours varies from 0 (55.2% of the respondents) to 120 hours (1.7% of the respondents).

The answers about the personal perception of work effort recognition showed that 48.1% feel appreciated, 33.3% do not feel appreciated, 9.3% do not feel appreciated at all and 9.3% feel very appreciated.

They consider themselves to be hard-working: 51.9% + 33.3%, only 5.6% and 9.3% admit not to be hard-working.

The perception about sufficient time to finish the work indicated that: 51.9% agree to have enough time, 9.3% totally agree, 27.8 do not agree with having enough time, 11.1% totally disagree.

Emergency medicine is a field with continuous learning environment. For the item "Learn new things": 59.3% total agree, 31.5% agree, 7.4% disagree and 1.9% total disagree. Also, the working environment is important for the item "Working with helpful colleagues" and the answer demonstrat-

ed: 48.1% agreement, 42.6% total agreement, 1.9% total disagreement and 7.4% disagreement. Learning from the mistakes of others: 35.2% total agreement, 57.4% agreement, 7.4% disagreement. The vast majority disagree with the difficulty of communicating with people of other culture (11.1 totally disagree and 57.4% disagree = 68.5%), 1.9% admit to have communication difficulties with people belonging to other culture.

The ED staff feel appreciated within the CPR team: 64.8% agree, 14.8% totally agree, 20.4% do not feel appreciated. Only 5.6% planned to quit the profession and 59.3% total disagree and 35.2% disagree.

When we analyzed the perception about the appropriate or inappropriate CPR, we also studied the perception of CPR futility. They could confidently express their doubts about the futility of the CPR: 11.1% total agree, 74.1% agree and 14.8% disagree.

The presence of the family during the CPR is still a subject of debate in ED and about this subject the population of the study demonstrated: agreement 11.1%, total agreement 3.7%, disagreement 53.7%, total disagreement 31.5%.

Necessity of debriefing time after CPR is consider important: total agreement 5.6%, agreement 57.4%, disagreement 31.5%, total disagreement 5.6%.

About the latest case with CPR during the recent professional life the answers demonstrated: ED personnel evaluation of the CPR opportunity: total agreement 14.8%, agreement 42.6%, disagreement 38.9%, total disagreement 3.7%.

Early recognition of CPR futility received the follow answers: 3.7% totally disagree, 7.4% disagree, 57.4% agree, 31.5% totally agree. These answers demonstrate the need to understand the CPR futility inside the ED staff.

The team leader appreciates the team effort during the latest experience in resuscitation: 35.2% totally agree, 53.7% agree, 11.1% disagree.

Regarding the perception of the ED personnel for inappropriate CPR, no correlation was found between the opportunity to start CPR and the patient particularities: the presence of the family, the presence of the DNR order, the age of the patient, the presence of dementia, the low quality of life, the initial shockable rhythm, the possibility of an organ donor, the patient age: child or adult.

There is a direct correlation of the initiation of the CPR with the site of the cardiac arrest: pre-hospital CPR is consider the right site to start CPR ($p = 0.354$), the pregnancy status of the female patient is a clear indication to start CPR ($p = 0.285$) but also the neoplasia in the terminal phase ($p = 0.410$).

We tried to explore the factors that made them feel the CPR is unnecessary and we obtained the next results:

- Inappropriate quality of CPR performed by witnesses until arrival: 38.9% very important, 37% important, 11.1% rather important, 13% unimportant
- Initial non-shockable rhythm: 22.2% very important, 42.6% important, 16.7% rather important, 18.5% unimportant
- The advanced age of the patient: 14.8% very important, 24.1% important, 22.2% rather important and 38.9% unimportant
- Patient with dementia: 5.5% very important, 20.4% important, 16.7% rather important and 57.4% unimportant
- Terminal neoplasia: 27.8% very important, 37% important, 14.8% rather important and 20.4% unimportant
- Low quality of life before CPR: 11.1% very important, 20.4% important, 20.4% rather important and 48.1% unimportant

DISCUSSION

From our knowledge, this is the first study conducted in ED in Romania, regarding the perception of futility of CPR, including emergency staff involved in cardiac arrest care, exploring potentially relevant organizational, clinical and work-related factors, as well as patient and situation-related factors, and relating these factors with patient outcome (ROSC). ED personnel was specifically asked about the latest cardiac arrest they encountered. As such the reported prevalence of perception of inappropriate CPR was based on a specific clinical event attended by the clinicians and not just on a vague general impression. Basing on our survey, we found that 57.4% of clinicians working in emergency departments and ambulance services perceived their latest CPR attempt as appropriate, and 42.6% perceived their last CPR attempt as inappropriate. Moreover, we found that the presence of objective indicators of poor prognosis only moderately increased the prevalence of perception of inappropriate CPR. In patients with non-witnessed non-shockable arrests, a group known for its highly unfavorable prognosis (4, 20) and a low rate of survival to hospital discharge, 22.2 % of ED considered it very important and 46.2% considered important the early recognition of futility of CPR. Unexpectedly, the neoplasia in terminal phase is consider an important situation of inappropriate CPR only by 64.8 % of ED personnel. These findings indicate that the majority of physicians and nurses are either unaware of the inappropriateness of their CPR attempt or only become aware of the potential consequences of their actions in extreme patient situations. The most important determinants of perception of inappropriate CPR were objective criteria such as non-shockable initial rhythm, non-witnessed arrest, older age and a poor first physical impression of the patient. This may indicate that perception of inappropriateness of appraisal and warranting team leaders to invite and consider the opinion of all experienced resuscitation team members, regardless of their role. Our results highlight the need of closed-loop systems assuring that all staff involved in resuscitation receive feedback on the results of their attempts. Debriefing and interdisciplinary ethical reflection on difficult patient cases are needed, more specifically when one team members has doubts about the appropriateness of resuscitation. More advance care planning conversations with patients and family are needed (26), based on realistic information about outcome of resuscitation thus avoiding inaccurate expectations of CPR (27). Compliance of clinicians once advance directives are established should be further improved (8, 25). This study has several limitations. First, the possibility that perceptions about appropriateness of CPR may have been affected by the resuscitation outcome. However, the questionnaire was structured in such a way that questions concerning outcome were listed at the very end. Second, data on ROSC and survival to hospital discharge were provided only for the study team and not for population included in the study.

CONCLUSIONS

Our findings suggest that emergency medicine professionals who are working on daily basis in an emergency system consider that performing the CPR maneuvers was appropriate in most of the cases but the ones who perceive CPR as inappropriate are entitled to express themselves regardless the role played inside the resuscitation team. Factoring this clinical judgment into

the decision to attempt resuscitation may reduce harm by excessive resuscitation attempts to a number of patients, facilitating DNR order in Romanian legislation for very strict defined situations and maybe a more dignified death for some people.

NEWS

RISK OF COVID-19 AMONG FRONTLINE HEALTHCARE WORKERS

The authors performed a prospective observational study of 2135190 individuals, comprised of front-line health-care workers and the general community who were voluntary users of the COVID Symptom Study smartphone application (app). From self-reported data obtained via this app, we found that front-line health-care workers had at least a threefold increased risk of COVID-19. Compared with front-line health-care workers who reported adequate availability of PPE, those with inadequate PPE had an increase in risk. However, adequate availability of PPE did not seem to completely reduce risk among health-care workers caring for patients with COVID-19. We also found that Black, Asian, and minority ethnic health-care workers might be disproportionately affected. The results of this study could help provide greater context for previous cross-sectional reports from public health authorities suggesting 10–20% of SARS-CoV-2 infections occur among health-care workers. The results offer individual-level data additionally accounting for workplace risk factors that complement these limited reports by providing a more precise assessment of the magnitude of increased risk among health-care workers during the initial phases of the COVID-19 pandemic. Taken in the context of the requirement for testing to establish a COVID-19 diagnosis, the range of results based on either reporting a positive test for COVID-19 or symptoms predictive of COVID-19 offer several complementary estimates for risk among front-line health-care workers (Nguyen LH, Drew DA, Joshi AD, et al. Risk of COVID-19 among frontline healthcare workers and the general community: a prospective cohort study. *The Lancet* 2020; 5(9): E475-483).

DEPRESSION OF THE ELDERLY PATIENTS: FOCUS ON A SINGLE CENTER STUDY

DEPRESSION OF THE ELDERLY PATIENTS: FOCUS ON A SINGLE CENTER STUDY (Abstract): Elderly patients may deny the existence of depressive symptoms due to the social disapproval of the diagnostic, as well as the difficulty of expressing the need for help regarding psychiatric symptoms. **The aim** of this study is to underline the importance of early diagnosis of depressive syndrome in the elderly patient and the clinical approaches. **Material and methods**: the criteria for inclusion in the study was represented by the patients over 65 years of age, diagnosed with depressive disorder, according with the criteria of ICD10, single episode or recurrent ones. **Results**: we included 77 patients and we evaluated the risk factors such as female sex, urban area of provenance, somatic comorbidities. **Conclusions**: Patients with onset of the depressive disorder over the age of 65 years old had a weaker response to treatment, an increased risk of progression to dementia and a higher rate of early mortality. In this context, the need for prophylaxis, as well as effective treatment, is crucial, using individualized therapies to the patient's needs. **Keywords**: DEPRESSION, EARLY DIAGNOSTIC, ELDERLY PATIENTS.

The World Health Organization (WHO) estimates that depression affects about 350 million people and also those in close contact with the patients. Depression is a condition that is often hidden, denied, and therefore underdiagnosed and treated (1). According to World Health Organization, in 2020 depression will be the second leading cause of disability, immediately after cardiovascular diseases. Depression is currently the fourth most common disease in the world and is one of the major human health problems (1, 2).

The Romanian League of Mental Health conducted a study related to the frequency of depression in a project carried out under the auspices of the European Union – "MINDFUL" (Mental Health Information and Determinants for European Level) in several European countries.(3) The research was conducted on a sample of about 2,400 people. Following this study, it was observed that the prevalence of major depressive episode at the time of examination was about 9%, and throughout lifetime for 21%. Depression is also twice as common in women. Romania ranks the third place in Europe in terms of the number of depressed

people, compared to the general population. Following the research carried out by the School of Public Health and Sanitary Management, the following were highlighted (2,3):

- significant increase in major depressive episode with age, from 2.1-2.6% (18-49 years) to 4.4-5.2% (over 50 years), with a growth rate of 1.2% for each age group (50-64 years and over 65 years);
- confirmation of the increased prevalence of major depressive episode during life (3.3% for all ages);
- twice as high in women (4.1% *vs.* 2.5%).

Depression in old age people is currently considered a distinct clinical entity because the clinical picture of depression have many different aspects compared to the clinical manifestation of depression in young people. The prevalence of depression is 12-45%, with an average of 20%. Depression in the elderly is considered by many practitioners to be a normal process and a consequence of aging. Old age can accentuate and at the same time suppress some symptoms of depression (4, 5). Depressive mood, the main symptom of depression, is masked in the elderly by some signs, such as: loss of appetite, sleep disorders or fatigue, which are usually not so intense in young people. The elderly present a poorer clinical picture than young patients, denying a number of important symptoms, such as feelings of guilt, suicidal ideation, and very often psychotic symptoms. Some of the most common depressive symptoms in the elderly are anxiety, somatic complains, cognitive impairment, psychomotor agitation, psychotic symptoms (6, 7).

The frequency of suicide attempts increases with age and especially male patients have an increased suicidal risk. Somatic comorbidities such as neoplasic diseases, stroke, myocardial infarction, kidney disease, but also loneliness and social isolation increase the risk of developing a specific plan for committing suicide. About two-thirds of elderly depressed patients have recurrent thoughts of death, including suicidal ideation, which are not easy to identify and 10-15% of them commit suicide (8). Psychotic symptoms in elderly patients diagnosed with depression is represented by delusional ideas with depressive content, uselessness, or guilt. Hallucinations have also been described, the most common being the auditory and visceral ones (9). Blazer identified a clinical picture specific to depression at elderly persons, characterized by depressive mood, psychomotor slowness, hypoprosexia with decreased ability to concentrate, constipation, low self-perception of health, cognitive deficit and association with a somatic disorder, picture that does not overlap with the specific diagnostic criteria in the Diagnostic and Statistical Manual or International Classification of Diseases (10, 11, 12). The clinical picture of depression in old age may be different compared to the clinical picture of depression in adulthood, due to certain factors like somatic comorbidities, anxiety, abuse of alcohol or a great consumption of medication, that may influence the clinical expression of depression and thus determined certain diagnostic difficulties (5). Also, elderly patients tend to minimize their feelings of sadness. They do not want to bother the doctor with emotional problems and instead describe an excessive concern for health or clear somatic symptoms, which can sometimes reach delusional intensities. Depressive mood varies from day to day, is often unaf-

fected by circumstances, but may still have a characteristic diurnal variation. In some cases, anxiety and psychomotor agitation may dominate the clinical picture, and mood swings may be masked by additional symptoms such as irritability, excessive alcohol consumption, histrionic behavior, exacerbation of pre-existing phobic or obsessive symptoms, or hypochondriac concerns.

Another important issue in the elderly patient is compliance with antidepressant treatment. Non-compliance with antidepressant medication in the elderly is more common than in young patients (13). It has been estimated that 70% of patients do not take between 25 and 50% of the medications prescribed to them (14). Many elderly patients with depression have substantial comorbidities, such as heart failure, diabetes, or cancer. Chronic illness is an additional risk factor for the development of depression. Optimizing medical conditions and selecting antidepressants to minimize drug interactions is relevant to managing depression. Mental disorders added to depression, such as anxiety and dementia, may have an additional effect on outcomes, but antidepressants appear to have similar efficacy in elderly and young patients (15). Although the presence of other diseases may make it difficult to diagnose depression, there is clear evidence that somatic comorbidities would substantially decrease the effectiveness of antidepressants.

MATERIAL AND METHODS

In a retrospective, descriptive study we assessed the importance of early diagnosis of depressive syndrome in elderly patients and their clinical approach, on the patients hospitalized at the "Socola" Institute of Psychiatry Iasi. One of the objectives of the study is to highlight the frequency with which depression has spread among the elderly population, analyzing data from years 2018 and the first semester of 2019. We included in the study all patients, over the age of 65 years old, which had the principal diagnostic of depressive episode, single of recurrent one, according with the criteria of diagnosis of ICD 10.

In order to obtain the information necessary for the statistical study, we used the following methods:

- clinical-anamnestic evaluation of hospitalized patients with the diagnosis of depressive disorder, over 65 years old;
- content analysis of medical documents registered in the archive.

Patients were evaluated by anamnesis, psychological evaluation, psychiatric interview, general clinical examination, paraclinical laboratory and imaging examinations.

The anamnesis and the dynamic observation of the patients during the hospitalization highlighted the dominant characteristics of the depressive syndrome, depending on the nature of the depressive episode for which they needed hospitalization, as follows: depressive mood, loss of appetite, sleeping disorders, fatigue, anxiety, somatic symptoms, cognitive impairment, psychomotor agitation, psychotic symptoms.

To make the differential diagnosis of depression with bipolar affective disorder, dementia or depressive symptoms induced by substance abuse (especially alcohol), paraclinical laboratory examinations (CBC, inflammatory syndrome, biochemistry, liver, and kidney tests) and imaging scan of the brain were performed.

For the statistical analysis of the data, we used the *Microsoft Excel* program, together with the *XLSTAT 2014* add-on for

MS Excel and the IBM *SPSS Statistics 20.0* program. The information obtained was recorded in Microsoft Excel files, being then statistically processed to highlight the relationship between clinical and paraclinical data of patients.

RESULTS AND DISCUSSION

Of the 111 cases of mild, moderate, and severe depressive single episode diagnosed during the year 2018, only 28 patients were over 65 years old. Of the 94 cases of mild, moderate, and severe depressive episodes diagnosed between 1.01.2019-30.06.2019, only 12 patients are over 65 years old.

In the case of patients diagnosed with recurrent depressive disorder in 2018, of the 288 cases, only 48 patients were over 65 years of age. In the period 01.01.2019-30.06.2019, out of the 226 cases diagnosed with recurrent depressive disorder, only 29 patients are over 65 years of age. Thus, the analyzed group comprises 77 patients.

In 2018, females were 2.7 times more frequently affected compared to males, while in 2019 women were three times more frequently diagnosed with recurrent depression compare to men (fig.1).

	women	men
2019	22	7
2018	35	13

Fig. 1. Distribution of the studied group by sex

It can also be seen that aging is another risk factor, the studied group having a minimum age of 65 years, a maximum age of 81 years for 2018 and 80 years for 2019, and the average age of the first diagnostic was 69 years old in 2018, respectively 72 years old in 2019.

Analyzing the situation of the numerical distribution of patients diagnosed with depressive disorder by age categories, it can be seen that in 2018 were diagnosed 240 patients aged 18-65 years, as opposed to the 197 patients diagnosed in the first half of 2019. Within the studied group, that

of patients over 65 years of age, the situation is as follows: in 2018, 48 patients were diagnosed with depressive disorder, while in the first half of 2019, 29 patients were diagnosed (fig. 2).

Another socio-demographic risk factor for the depressive disorder analyzed was the environment of residence, being highlighted the fact that in both periods, patients coming from urban areas are more affected compared to those from rural areas (fig. 3).

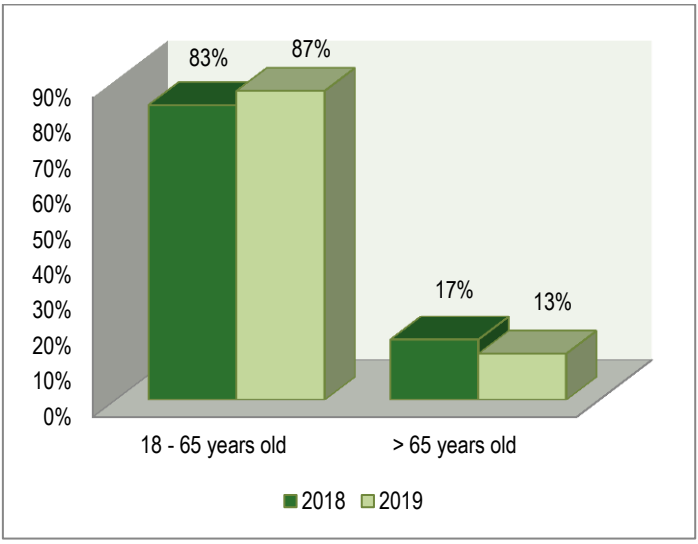

Fig. 2. Distribution of patients diagnosed with depressive disorder by the age at diagnostic

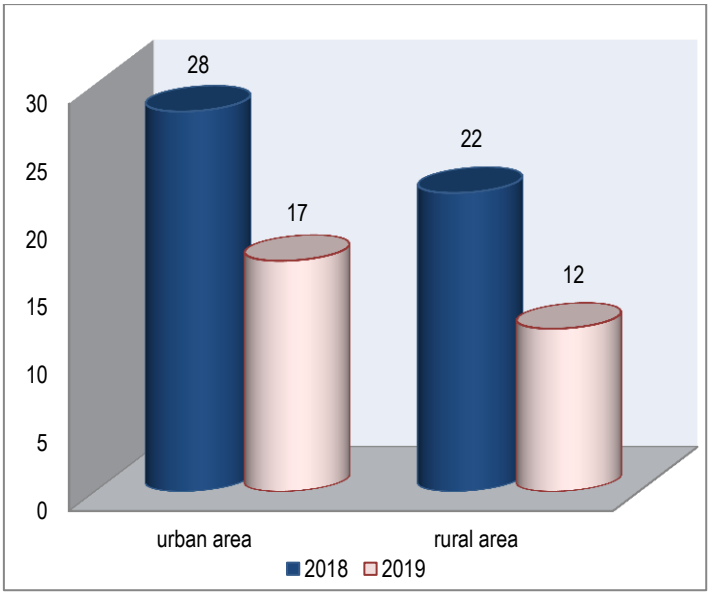

Fig. 3. Distribution of patients diagnosed with depressive disorder by area of provenance

Unfortunately, most patients diagnosed with recurrent depressive disorder during 2018 and in the first half of 2019 presented with a severe current episode with or without psychotic symptoms. In 2018, of all patients 69% were diagnosed with a severe current episode without psychotic symptoms, 29% had a current episode with psychotic symptoms and only 2% were recorded with a moderate current episode. Between 01.01.2019 and 30.06.2019 the situation is not at all better, most patients (72%) being diagnosed with a severe current episode with psychotic symptoms, while the remaining 28% were patients who presented with a severe current episode without psychotic symptoms. It can be seen that in the first half of 2019 alone, 29 patients were already registered compared to the 48 patients diagnosed in 2018, and most of them presented with the most severe form of a recurrent depressive disorder, namely episode severe with psychotic symptoms (fig. 4).

	recurrent depression-mild form	recurrent depression-moderate form	recurrent depression-severe form	recurrent depression-severe form with psychotic features
2018	0	1	33	14
2019	0	0	8	21

Fig. 4. Distribution of patients diagnosed with depressive disorder - severity form

Data on the prevalence of depression among the population over the age of 65 vary from 1-5%. The rate of depression is higher among the elderly female population, but without significant differences (16). According to data provided by a study conducted by Blazer in 2003 only in 15% of cases elderly patients show clinically significant symptoms specific for depression (7).

Cognitive decline is still the heaviest burden of the elderly, being considered by many practitioners a normal process and a consequence of aging, this contributing to an underdiagnosis and also to the delay of the administration of an adequate treatment that could minimize, in the long term, both the costs associated with late diagnosis and the complications of the pathology for this patients.

Early diagnosis and prevention of the depressive disorder are particularly important, given the fact that elderly population will triple from 1.9 billion in 2050, compared to 672 million in 2005. Increasing life expectancy to 82 years in developed countries will determine the number of the population over 85 years to reach 6.6 million in 2020, compared to 5.7 million today. As the number of patients diagnosed with mental disorders, especially mood disorders, will be 15 million by 2030, depression in old age will be one of the costliest conditions due to increased risk of suicide, somatic comorbidities, decreased functionality and the quality of life of both the patient and the family (1,15).

CONCLUSIONS

The correct diagnosis of depression subtypes is the guide in selecting and establishing the most appropriate therapeutic modalities. Depression in old age, one of the most common nosological entities, is often underdiagnosed and undertreated. Early diagnosis and prevention are particularly important. In 2030, depression in old age will be one of the costliest conditions due to increased risk of suicide, somatic comorbidities, decreased daily functionality and quality of life for both the patient and the family. As the costs are 2.3 times higher compared to the adult population, the development of a model that allows personalized treatment of depression in old age is a challenge for both clinicians and researchers (1, 15).

The burden of the depressive disorder is felt not only by the individual affected by this disease, but also by the family of the suffering person, by increasing stress and decreased quality of life, major effects on financial status, professional and socially consequences, as well as at the level of society as a whole, through a series of huge social and economic costs.

GASTROINTESTINAL RESPONSIVE POLYMERIC NANOPARTICLES FOR ORAL DELIVERY OF INSULIN: OPTIMIZED PREPARATION, CHARACTERIZATION AND *IN VIVO* EVALUATION

Biomacromolecules have transformed our capacity to effectively treat diseases; however, their rapid degradation and poor absorption in the gastrointestinal (GI) tract generally limit their administration to parenteral routes. An oral biologic delivery system must aid in both localization and permeation to achieve systemic drug uptake. Inspired by the leopard tortoise's ability to passively reorient, we developed an ingestible self-orienting millimeter-scale applicator (SOMA) that autonomously positions itself to engage with GI tissue. Gastrointestinal responsive polymeric nanospheres (NPs) based on hydroxypropyl methylcellulose phthalate (HPMCP) were prepared using spontaneous emulsification solvent diffusion method for improved oral administration of insulin. The NPs were prepared under optimized conditions have an encapsulation efficiency of 90% and a particle size of about 200 nm. *In vitro* drug release experiments demonstrated that the NPs exhibited a gradient release profile of loaded drug when the pH value gradually increased from 3.0 to 7.4. Enzyme resistance experiments showed that under simulated gastrointestinal conditions, the NPs protected more than 60% of the drug from being degraded by trypsin. The oral hypoglycemic experiments revealed that insulin-loaded NPs could significantly reduce blood glucose levels in diabetic rats with a relative bioavailability of 8.6%. *Ex vivo* imaging investigation of rat tissues showed that the drug-loaded NPs could promote the absorption of insulin in the ileum and colon. The work described here suggests that the gastrointestinal responsive polymeric NPs may be promising candidates for improving gastrointestinal tract delivery of hydrophilic biomacromolecules. Accordingly, the results indicated that HPMCP NPs with gastrointestinal stimuli responsiveness could be a promising candidate for oral insulin delivery. (Fang Y., Wang Q, *et al.* Gastrointestinal responsive polymeric nanoparticles for oral delivery of insulin: optimized preparation, characterization and *in vivo* evaluation, *J Pahr Sci* 2019; pii: S0022-3549(19)30253-9).

DIAGNOSIS AND THERAPEUTIC MANAGEMENT OF NAIL PSORIASIS

DIAGNOSIS AND THERAPEUTIC MANAGEMENT OF NAIL PSORIASIS **(**Abstract**) Aim:** To identify the comorbidities associated with nail psoriasis and its therapeutic management. **Material and methods:** A 4-year retrospective analytical study which included 527 patients admitted to the Dermatology Department of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital from Iași. **Results:** The frequency of cases without nail or arthropathic psoriasis was much higher (88.89% of cases) compared to 32.97% of cases associating arthropathic and nail psoriasis (χ^2 = 37.93, p <0.00001). Cases with nail psoriasis were significantly more commonly associated with severe forms of psoriasis with PASI scores higher than 20 (49.57% cases compared to 28.89%, Z = 3.69, p = 0.0001, and to 35.6 %, Z = 2.42, p = 0.008) and similarly, with DLQI scores higher than 20 (52.73% compared to 28.88%, Z = 4.41, p <0.00001 and to 32.54%, Z = 3.79, p = 0.00008). In patients with nail psoriasis, the highest frequency of cases with favorable outcome was obtained with biological treatment (80.85% compared to 39.86% of those with topical treatment, Z = 4.85, p <0.00001 and compared to 43.33% of those with topical and systemic immunosuppressive therapy, Z = 3.93, p = 0.00004). **Conclusions:** The presence of arthropathic psoriasis may be a risk factor for nail psoriasis, and its absence may be a protective factor against nail psoriasis. Severe forms may lead to quality of life (QOL) impairment with unfavorable, stationary and undulating course. Although nail psoriasis is usually investigated by clinical examination, the diagnosis of incipient form of disease is needed.
Keywords: NAIL PSORIASIS, PASI SCORE, DLQI (DERMATOLOGY LIFE QUALITY INDEX), ARTHROPATHY, THERAPEUTIC RESPONSE.

Psoriasis is no longer considered just a skin disease but rather a systemic chronic inflammatory disease associated with a substantial risk of increasing the morbidity rate that involves the skin, nails, joints, and other organs (1, 2). Nail disease is an important issue in dermatological practice and nail psoriasis may be present alone or associated with skin lesions. Currently, nail psoriasis associated with an inflammation of the nail bed has a prevalence ranging from 10 to 80% of psoriatic patients (3).

Psoriasis may affect the entire nail unit including the nail matrix, the nail bed

and/or the hyponychium component. Up to 30% of the psoriatic patients have arthropathic involvement (4). Symptoms of arthropathic psoriasis include swollen painful joints, causing discomfort and limiting patient mobility, usually the skin lesions precede the arthritis by 5-10 years. Over time, erosions can cause significant deformities and permanent invalidation (4). The anatomical relationship between the distal phalanx and the nail unit determines the correlation between arthropathic psoriasis and nail changes associated with systemic enthesopathy (5). Scoring systems are useful in assessing disease severity and monitoring therapy response (6). Visual examination may reveal leukonychia and loss of nail plate transparency due to involvement of mid-matrix, whereas pitting is caused by the involvement of the proximal portion of the nail matrix. Exocytosis of leukocytes beneath the nail plate leads to "oil drop" or "salmon patch" as clinical aspects, and splinter hemorrhages may appear due to capillary fragility. Another clinical form of nail psoriasis includes subungual hyperkeratosis and distal onycholysis and is caused by the parakeratosis of the distal nail bed. When the entire nail matrix is involved, the nail plate has a diffuse white appearance (3). Increased nail plate and bed thickness were reported in psoriatic patients without apparent clinical disease (7).

One of the aims of our study was to identify the clinical parameters and comorbidities correlated with nail and arthropathic disease and to evaluate their therapeutic management in psoriatic patients.

MATERIAL AND METHODS

We conducted a 4-year retrospective analytical study (2016-2019) including 527 patients diagnosed with psoriasis admitted and treated to the Dermatology Department of the Iasi "St. Spiridon" County Clinical Emergency Hospital. The study was approved by the Clinical Research Ethics Committee of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital Iași and Clinical Research Ethics Committee of the Iasi "Grigore T. Popa" University of Medicine and Pharmacy. Data were extracted from the medical records in accordance with currents regulations, and security and confidentiality were warranted.

The inclusion criteria were positive clinical and/or histopathological diagnosis of psoriasis with the presence of at least one clinical form of the psoriasis disease such as plaques *vulgar psoriasis*, inverse or guttate psoriasis, palmoplantar pustular or generalized pustular psoriasis, or erythrodermic psoriasis. Special locations including the scalp, palmoplantar area, nails, genital area, large folds, and facial involvement were analyzed. Moreover, the comorbidities, such as psoriatic arthropathy including asymmetric oligoarthropathy, distal interphalangeal, mutilating arthritis, spondylitis, or rheumatoid type with distal symmetrical poly arthropathy were assessed by the rheumatologists. Exclusion criteria were uncertain clinical or histopathological psoriasis diagnosis and incomplete medical records that might affect the statistical results.

Nonparametric data from categorical variables, frequencies, and parametric data according to various scores calculated by clinicians in order to assess psoriasis severity were used. Psoriasis Area Severity Index (PASI) is an international dermatologic index used to express the severity of psoriasis which combines the severity (erythema, induration, and desquamation) and

percentage of affected area and has values with ranges from 0 to 72 (4). The Dermatology Life Quality Index (DLQI) is a questionnaire filled out by the patient and the clinician that assesses patient's QOL impairment by summing the score for each question resulting in a maximum of 30 and a minimum of 0. The higher the score, the more QOL is impaired (8). Depending on the values of this score along with DLQI score psoriasis can be classified in one of the following severity levels: mild (PASI<10, DLQI<10), moderate-severe (PASI >10) or severe psoriasis (PASI>10 and/ or DLQI >10, or when psoriasis is defined as pustular, erythrodermic or arthropathic psoriasis, or PASI <10 but with significant impairment of disease) (9).

Statistical analysis. The data were processed using version 7 of *Statistica* software. The parameters and their frequencies were analyzed and the statistical significance of differences between the mean values were assessed according to the grouping variables. The significance of the differences between the frequencies was evaluated with χ^2 *test*, appreciating that differences were as significant when the calculated value of the χ^2 test was higher than the critical value corresponding to the significance p value of 0.05. If percentages are compared, the significance of differences will be assessed using the *Z test*, considering as significant the differences located at a significance p value of 0.05 or less.

RESULTS

The study included 527 psoriatic patients with a mean age in men higher by an average of 3.06 years, the difference being statistically significant (t = 1.98, p = 0.048) (tab. I).

TABLE I

Average age difference by sex

Variable	Average		t	DF	p	N		Standard Deviation	
	Women	Men				Women	Men	Women	Men
Age	**51.11↓**	**54.17**	1.98	525	**0.048**	229	298	18.96	16.47

The frequency of the association of arthropathic psoriasis with nail psoriasis was reported for total cases of arthropathic psoriasis (tab. II).

TABLE II

Frequency of arthropathic psoriasis and nail psoriasis association

Arthropathic psoriasis	Nail psoriasis				Total		χ^2	p
	Presence		Absence					
Presence	**60**	**32.97**	122	67.03	182	100	37.93	**<0.00001**
Absence	38	11.01	**307**	**88.99**	345	100		
Total	98	18.60	429	91.40	527	100		

Since the calculated value χ^2 = 37.93 is significantly higher than the critical value at p <0.00001, the hypothesis of a significant relationship between arthropathic psoriasis and nail psoriasis is accepted, especially in the sense that the absence of arthropathic psoriasis may be a protective factor against nail psoriasis, given that

88.99% of cases without arthritic psoriasis, do not have nail psoriasis, and only 11.01% of patients with nail psoriasis had no arthropathic psoriasis.

Assessment of the relationship between nail psoriasis, PASI and DLQI severity scores (fig.1) showed that the cases with nail psoriasis were significantly more frequently associated with PASI scores higher than 20 (49.57% compared with 28.89% cases with PASI scores <10, Z = 3.69, p = 0.0001 and compared with 35.6 % with PASI scores between 10-20, Z = 2.42, p = 0.008). Similarly, cases with nail psoriasis were significantly more frequently associated with DLQI scores higher than 20 (52.73% compared to 28.88% cases with DLQI scores <10, Z = 4.41, p <0.00001 and compared to 32.54% with DLQI scores between 10-20, Z = 3.79, p = 0.00008).

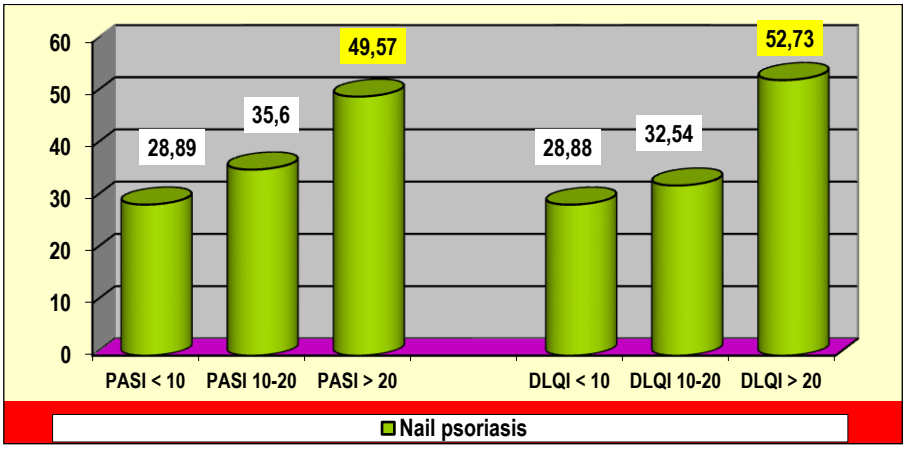

Fig. 1. Frequency differences in PASI and DLQI scores in patients with nail psoriasis

Comparison of the frequency of treatments recommended to patients with nail psoriasis highlighted the following significant differences (fig.2):

- the frequency of topical corticosteroid treatment was significantly lower compared to systemic treatments with methotrexate (34.89% compared to 50%, Z = 3.31, p = 0.005) and retinoids (34.89% compared to 58.33%, Z = 1.68, p = 0.046) and biological therapy (34.89% compared to 50.45% with biological therapy, Z = 3.04, p = 0.001)

- the frequency of topical treatment with vitamin D3 analogues was significantly lower than that of systemic treatment with methotrexate (35.62% compared to 50% with methotrexate, Z = 2.02, p = 0.02) and biological treatment (35.62% compared to 50.45% with biological treatment, Z = 1.98, p = 0.02).

The relationship between nail psoriasis and disease course was analyzed (tab. III) and by comparing the treatment response in patients with nail psoriasis we found that:

- the frequency of cases with favorable course was significantly higher after biological treatment (80.85% compared to 39.86% of those on topical corticosteroids and vitamin D3 analogues, Z = 4.85, p < 0.00001 and 43.33% of those on topical and systemic treatment with methotrexate, corticosteroids, or retinoids in pustular or erythrodermic psoriasis, Z = 3.93, p =

0.00004);

- the frequency of cases with unfavorable course was significantly higher in patients on topical treatment (13.04% compared to 4.26% of those on biological treatment, Z = 1.67, p = 0.047);

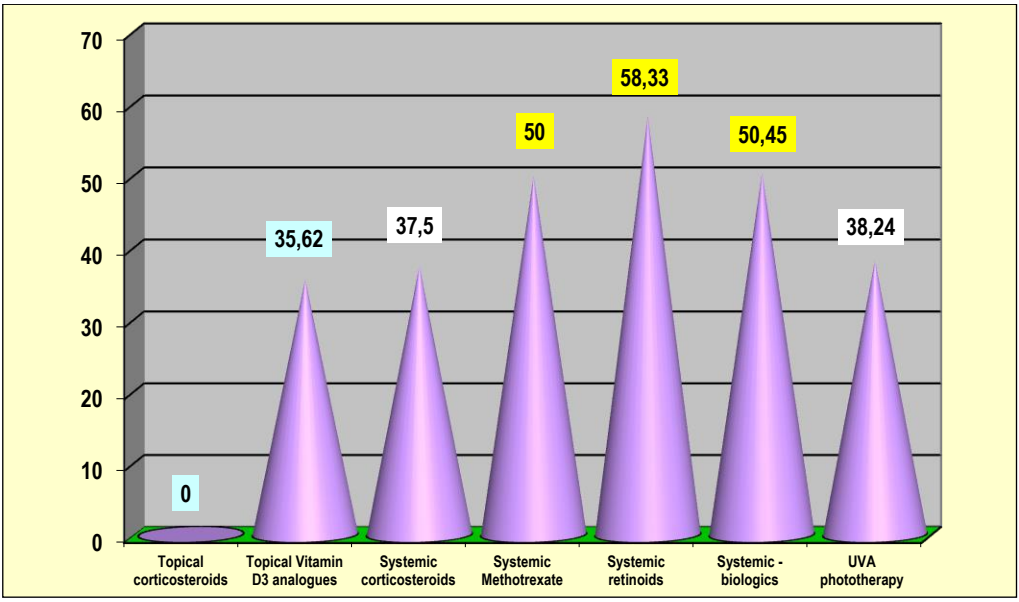

Fig. 2. Differences in the frequency of treatment in patients with nail psoriasis

TABLE III

Response to treatments administered to patients with nail psoriasis

Effect	Therapy						Significance of the difference	
	Topical		Topical and systemic		Biologic			
	N	%	N	%	N	%	Z	p
Favorable	55	**39.86↓**	26	**43.33↓**	38	**80.85**	0.46; 4.85; 3.93	0.32;**<0.00001;0.00004**
Unfavorable	18	**13.04**	5	8.33	2	**4.26↓**	0.95; 1.67; 0.84	0.17; **0.047**; 0.20
Stationary	24	**17.39**	10	**16.67**	0	**0↓↓**	0.12; 2.19; 3.06	0.45; **0.0007**; **0.001**
Undulating	41	**29.71**	19	**31.67**	7	**14.89↓**	0.28; 2.00; 2.01	0.39; **0.02**; **0.02**
Total	138	100	60	100	47	100		

- the frequency of cases with stationary course was significantly higher for topical treatment (17.39% compared to 0% of those on biological treatment, Z = 2.19, p = 0.0007) and on topical and systemic treatment (16, 67% compared to 0% of those on biological treatment, Z = 3.06, p = 0.001);

- the frequency of cases with undulating course was significantly higher with topical treatment (29.71% compared to 14.89% of those with biologic systemic treatment, Z = 2.00, p = 0.02) and topical and systemic treatment (31.67% compared to 14.89% of those with biological treatment, Z = 2.01, p = 0.02).

DISCUSSION

Current available data revealing nail in-

volvement in 10-80% of psoriatic patients (3) are confirmed by our study results; thus, of the 527 psoriatic patients 98 presented different clinical forms of onychopathy (18.6%). Other studies (10, 11, 12) estimated that up to 70-80% of patients with plaque psoriasis have nail involvement.

The prevalence of arthropathic psoriasis in patients affected by nail psoriasis ranges from 6% to 40% depending on the study design (13). Plaque psoriasis and nails psoriasis have been associated with the likelihood of developing psoriatic arthropathy. Similarly, special locations including the scalp or flexural areas have been associated with the risk of developing arthropathy with severity related to the magnitude of the cutaneous lesions. Reported data indicate that the tightest correlation with arthropathic psoriasis has been found in patients with nail disease (14). Verifying the hypothesis of a relationship between comorbidities and nail psoriasis using the χ^2 test, the results of our study revealed that there is a significant relationship between the presence of arthropathic psoriasis and nail psoriasis. The calculated value of the test $\chi^2 = 37.93$ is significant at $p < 0.00001$, and the existence of a significant relationship between arthropathic psoriasis and nail psoriasis is validated. The fact that the frequency of cases without arthropathic psoriasis and without nail psoriasis is much higher (88.89% of cases) compared to 32.97% associating arthropathic and nail psoriasis, leads to the conclusion that the absence of arthropathic psoriasis is a protective factor against nail psoriasis.

Nail involvement is associated with greater impairment of patients' QOL and also with moderate-to-severe skin disease (15). When assessing a total of 661 patients, Armesto S. *et al* (16) reported that 47.4% of patients were diagnosed with nail psoriasis and the group of patients with nail disease had more severe psoriasis (12.82 *vs.* 8.22 points) on the PASI index and included a larger percentage of patients with psoriatic arthritis (29.7% *vs.* 11.5%) (16). Our study results indicate that cases with nail psoriasis were significantly more commonly associated with severe forms of psoriasis with PASI greater than 20 (49.57% compared to 28.89%) and DLQI scores greater than 20 (52.73% compared to 28.88% cases).

Systemic therapy including phototherapy should be recommended to psoriatic patients with a moderate-to-severe form of disease defined with a body surface area (BSA) over 10%, or a PASI score>10 and/or a DLQI score >10, or when the disease is localized but presents significant functional impairment such as severe nail disease or involvement of special location such as palmoplantar area, scalp, face, or flexural areas (14, 17). Moreover, treatment recommendations (18, 19, 20) regarding nail psoriasis are related to the severity and matrix or bed involvement. Intralesional steroid injections are indicated in the case of matrix involvement alone. Topical corticosteroids alone or in combination with vitamin D3 analogues for nail psoriasis are limited to the nail bed affection, whereas systemic treatment including acitretin, methotrexate, cyclosporine or biologics may be indicated when more than 3 nails are involved according to clinical manifestation and severity scores. Although nail psoriasis is usually investigated by clinical examination, imaging techniques such as High Frequency Ultrasound or Dermoscopy are needed to diagnose incipient forms of nail psoriasis or to monitor the disease course under therapy (21, 22). In our study the frequency of topical corticosteroid treatment and similarly, the

frequency of topical treatment with vitamin D3 derivatives was significantly lower compared to systemic treatment with methotrexate, with retinoids, and biological therapy. In patients with nail psoriasis, the highest frequency of cases with favorable course resulted after biological systemic treatment whereas the unfavorable, stationary and undulating course were significantly higher following topical treatment and topical and systemic treatment with immunosuppressive therapy.

CONCLUSIONS

Based on the results of the present study, nail psoriasis is an association of an inflammation of the nail bed accompanied possibly by arthropathic psoriasis which may lead to QOL impairment in severe forms of disease. The presence of arthropathic psoriasis may be a risk factor for nail psoriasis.

The severity of nail involvement does not always parallel the intensity of cutaneous lesions, and subclinical forms of disease may be present. Therefore, non-invasive techniques such as High Frequency Ultrasound or Dermoscopy to diagnose subclinical forms of nail psoriasis progression or therapeutical response are necessary in current dermatology practice. Nail psoriasis management should be individualized, and it depends on the involvement of skin and/or joints, the number of affected nails influencing the choice of topical and/or systemic therapies.

NEWS

THE RELATIONSHIP BETWEEN EXERCISE CAPACITY AND NEUTROPHIL/LYMPHOCYTE RATIO

Neutrophil/lymphocyte ratio (NLR) has recently been used as a potential marker to determine inflammation in cardiac and non-cardiac diseases. Functional capacity, expressed as metabolic equivalent (MET) based on treadmill test, is one of the major prognostic factors in individuals with heart failure. The NLR value, with a threshold level of 2.26, predicts a poor functional capacity with the sensitivity of 83% and specificity of 69%. Therefore, NLR was proposed as a useful tool to evaluate exercise performance of patients with heart failure. Similarly, NLR could also be used to predict functional capacity of patients before cardiac rehabilitation program. (Okan S. The relationship between exercise capacity and neutrophil/lymphocyte ratio in patients taken to cardiopulmonary rehabilitation program. *Bratisl Lek Listy* 2020; 121(3): 206-210).

STUDYING SOME POSSIBLE IRRITABLE BOWEL SYNDROME MANIFESTATIONS IN COVID-19 PATIENTS

STUDYING SOME POSSIBLE IRRITABLE BOWEL SYNDROME MANIFESTATIONS IN COVID-19 PATIENTS (Abstract): The starting point of the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) pandemic is a highly debated topic today. Despite the fact that a multitude of hypotheses have been issued in this context, this new strain beta-coronavirus is not only highly contagious, but also rapidly transmitted interpersonally through the perpetually disrupting the homeostasis. It constantly affects the lungs, and also the digestive tract according to the latest reports following its binding to the angiotensin-converting enzyme 2 (ACE2) receptors. **Material and methods:** In the present study we aimed to explain and describe some gastrointestinal deficiencies exhibited by the positive patients Therefore, the Visual Analogue Scale-IBS (VAS-IBS) questionnaire was applied to a group of positive patients (n = 22) and compared to their sex-matched controls (n = 22). The confirmation for the SARS-CoV-2 infection was carried out by specific RT-qPCR testing. **Results:** We observed that the overall scores attributed to the spectrum of Physical symptoms, Mental health and Quality of life are significantly different among the COVID-19 group dependent on sex than in the control group. However, we did not find significant differences in terms of shape and stool consistencies (as evaluated by Bristol scale). **Conclusions:** In this study, we showed that several gastrointestinal symptoms (as evaluated by VAS-IBS scale) could occur during or following SARS-CoV-2 infection. **Keywords:** COVID-19, SARS-COV-2, IRRITABLE BOWEL SYNDROME, VISUAL ANALOGUE SCALE FOR IBS, GASTROINTESTINAL MANIFESTATIONS, CLINICAL FEATURES.

Even though the human coronaviruses (HCoVs) are responsible for a low percentage in terms of annual enteric, respiratory and hepatic infections, the ongoing pandemic has placed not only Europe but the entire world in a state of emergency (1). Having as epicenter the city of Wuhan and as a consequence of the uncontrolled spread, the latest statistics issued by the World Health Organization (WHO) are showing increasing number of deceased patients.

The Severe Acute Respiratory Syndrome

Coronavirus 2 (SARS-CoV-2) is a new beta-coronavirus which is highly contagious and easily transmitted from person-to-person that has as intermediate host the Chinese rufous horseshoe bat - *Rhinolophus sinicus* (2). Compared to SARS that affected China in February 2003, its pathogenesis is quite similar to that of Middle East Respiratory Syndrome (MERS) and includes fever, dyspnea, cough, and invasive lesions on both lungs (3).

In this way, adults over the age of fifty-five and those suffering from chronic diseases are at a higher risk, which is directly reflected by the number of deaths (4-9). While most of the patients have fever and acute manifestations of the respiratory tract, several studies have also demonstrated that patients display gastrointestinal (GI) deficiencies. Diarrhea is predominant as well as the most common symptom. Indeed, the incidence varies between low, up to medium, some of them occurring before to respiratory symptoms (10).

Recently, it was observed that several antivirals used for COVID-19 treatment could lead to GI reactions similar to those observed during and following COVID-19. In this way, extensive evidence showed that hydroxychloroquine induces gastrointestinal impairments leading to diarrhea (11). Moreover, Bescos *et al.*, (12) suggested that some disinfecting agents (e.g. chlorhexidine) widely used to eradicate SARS-CoV-2 could lead to the same impairments.

On the other hand, considering that the GI symptoms occurring in irritable bowel syndrome (IBS) are strongly tied to exposure to chronic stress and elevated stress experiences such as quarantine and physical distancing consisted in a high level of stress (13,14), this study aimed to evaluate the possible occurrence of IBS symptoms in COVID-19 patients. Thus, a group of patients infected with SARS-CoV-2 and their sex-matched controls were recruited and the VAS-IBS scale was applied.

MATERIALS AND METHODS

Study participants

A total number of forty-four participants between 17-70-years old from Orygin Clinic, Iasi, Romania was enrolled in this study and subsequently divided into two equal small groups as follows: COVID-19 (male, n = 10 and female, n = 12) and their sex-matched controls (male, n = 10, and female, n = 12). All individuals were admitted into the study between June 15 to October 30. The main inclusion criteria of the participants in the study were the manifestation of the specific phenotype, with particular emphasis on the reporting of gastrointestinal ones such as fever, nausea, vomiting, and diarrhea, as well as the suspicion of infection. Were not considered eligible those with associated chronic diseases, drug or other substances usage or with an ongoing pregnancy.

Visual Analogue Scale for Irritable Bowel Syndrome

VAS-IBS scale was applied according to Bengston *et al.*, (15,16) guidelines following translation and adaptation to Romanian language and ROME IV criteria. It is a questionnaire which consist of 7 VAS scales regarding abdominal pain, diarrhea, constipation, bloating/gases, vomiting/nausea, psychological well-being and the intestinal symptoms' influence on daily life. Both groups received to fill a VAS-IBS questionnaires following a RT-qPCR detection test of SARS-CoV-2.

Ethical approval

The present study was approved by the

local committee (no 1/564/10/06/2020). Also, it was conducted according to the Helsinki Declaration of human rights and national and European regulations on Biomedical Research. Participants agreed and individually signed written informed consent for their voluntary contribution to this study.

Statistical analysis

Cumulative descriptive statistics regarding all responses were computed for each item of the VAS-ISB questionnaire with a CI of 95%. Statistical analyses were carried out using Minitab 19 software (Minitab Inc., 2019). Standard statistical analysis (One-way Single Factor ANOVA, Student's t-test) was applied, and all results were expressed as mean ± S.E.M. F values for which $p < 0.05$ were regarded as statistically significant.

RESULTS

In this study, we observed that the scores of the visual analogue scale-IBS administered to the participants were significantly higher in the COVID-19 patients, as compared to sex-matched healthy controls. More precisely, the intensity of the physical symptoms such as abdominal pain ($p < 0.001$), diarrhea ($p < 0.001$), constipation ($p < 0.001$), and bloating/gases ($p < 0.001$) was significantly elevated in the SARS-CoV-2-infected patients as showed in first figure.

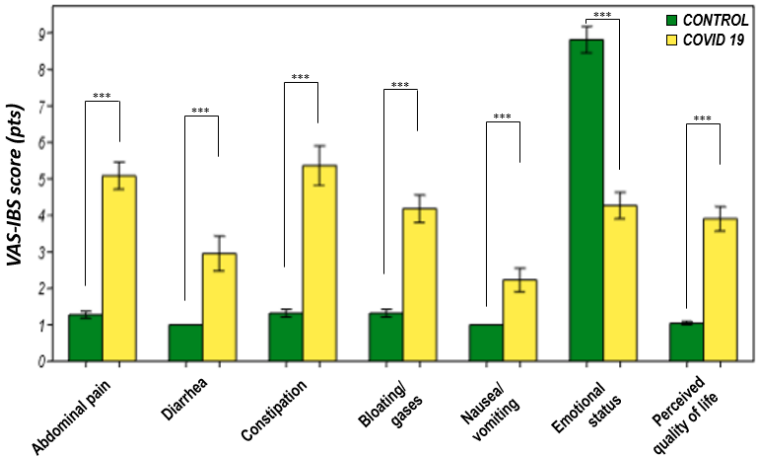

Fig. 1. VAS-IBS items scores in IBS patients and age and sex-matched healthy controls. The results are expressed as mean scores of VAS-IBS items ± SEM (n = 10 M and 12 F for each group, **p < 0.01, ***p < 0.001)

Regarding the sex differences, we observed that however no significant difference between healthy age and sex-matched controls was noted in terms of men vs women perception of abdominal pain and stool consistency, these change significantly in the COVID-19 patients. In this way, our results suggested that male COVID-19 patients are prone to exhibit constipation, while female COVID-19 reported diarrhea (fig. 2).

Furthermore, while analyzing the results stratified by sex, we observed that COVID-19 women significantly experienced frequent bloating ($p < 0.001$) and vomiting ($p < 0.01$) as compared to male COVID-19.

However, no significant differences were observed regarding the urge to defecate and the perceived sensation of incomplete defecation (fig. 3).

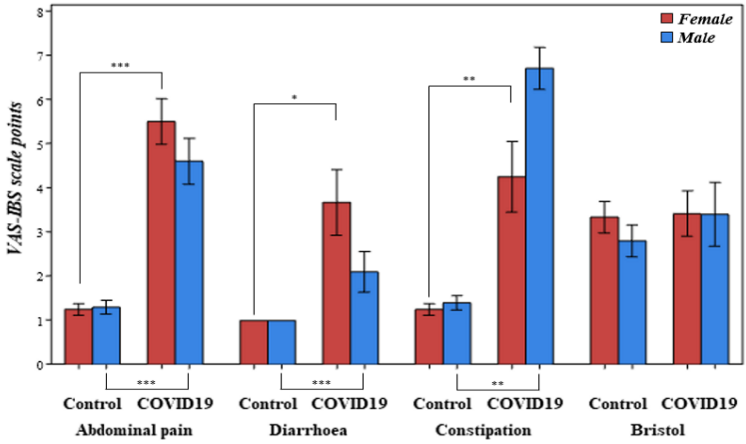

Fig. 2. The sex-stratified evaluation of abdominal pain, diarrhea and constipation severity, and Bristol score in COVID-19 patients as compared to sex-matched healthy controls. The results are expressed as mean scores of VAS-IBS items ± SEM (n = 10 M and 12 F for each group, *p <0.05, **p <0.01, ***p <0.001)

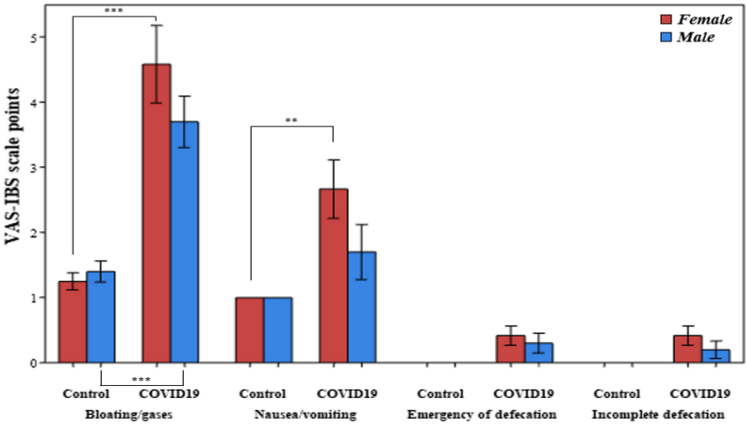

Fig. 3. The sex-stratified evaluation of bloating/ gases, nausea/ vomiting, emergency of defecation, and incomplete defecation occurrence in COVID-19 patients as compared to sex-matched healthy controls. The results are expressed as mean scores of VAS-IBS items ± SEM n = 10 M and 12 F for each group, **p <0.01, ***p <0.001)

Finally, the VAS-IBS scale also includes 2 items regarding the psychosocial and mood status in the context of the perception and changes brought by the GI symptoms burden. In the general tendency could also be seen while further stratifying the groups considering sex is required. Thus, both male and female patients stated

that their emotional status was felt lower in correlation to the perceived GI symptoms, as compared to healthy controls (p< 0.001). Similarly, both male and female patients stated that GI symptoms are affecting their quality of life in contrast to healthy sex and age-matched controls (p <0.001) (fig. 4).

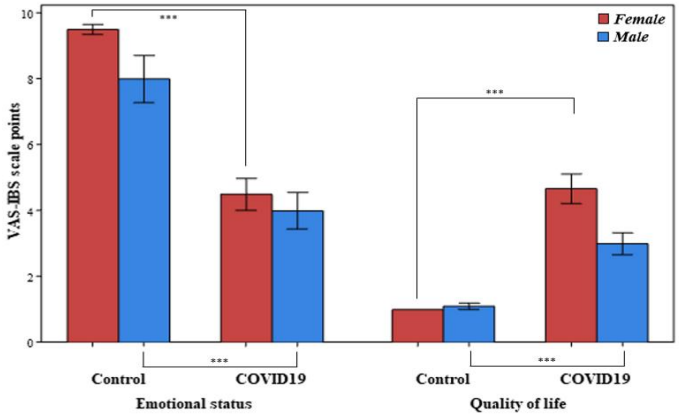

Fig. 4. The sex-stratified evaluation of the emotional status and quality of life in COVID-19 patients as compared to sex-matched healthy controls. The results are expressed as mean scores of VAS-IBS items ± SEM (n = 10 M and 12 F for each group, ***p <0.001)

Regarding the Bristol scale (p = 0.0048) (fig. 5), which is a newly added criteria for assessing the IBS subtypes, we observed that it can be seen that the frequency of diarrhea changes. More precisely, this GI disturbance is predominant in both groups-control (35%) and COVID-19 (50%). However it is hard to establish the exact cause-infection, medication or stress based on our study, given that Roque and Bouras (17) suggest in parallel that approximately 20% of the general population suffer from diarrhea.

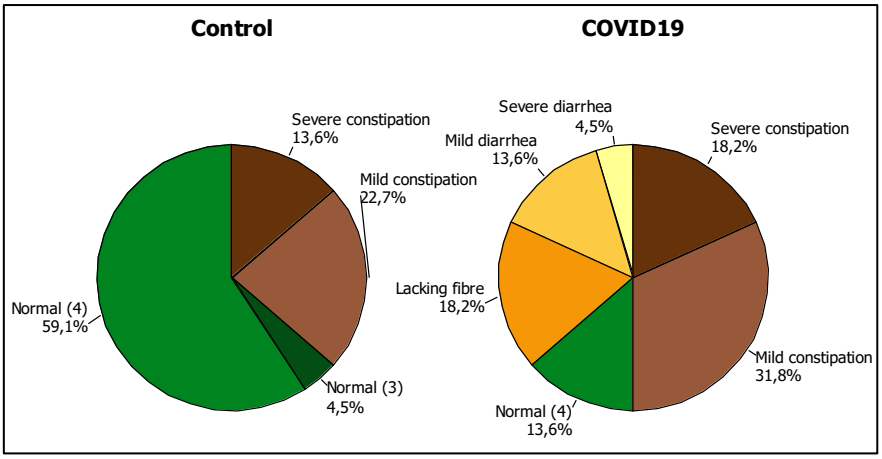

Fig. 5. Differences of the Bristol scale in terms of constipation versus diarrhea prevalence between the COVID-19 group and their sex-matched controls

The same discussion applies for the other two logical parameters, 'Incomplete defecation' (p = 0.008) and 'Emergency of defecation' (p = 0.003), considering that we observed a prevalence of 31.8% for 'Incomplete defecation' and 36.4% for 'Emergency of defecation' (figs. 6 and 7).

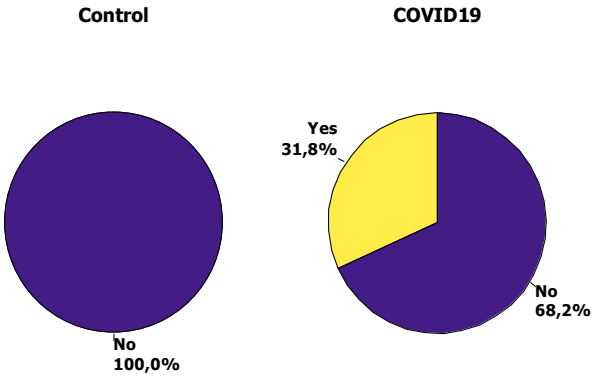

Fig. 6. The overall prevalence of 'Incomplete defecation' between the COVID-19 group and their sex- matched controls

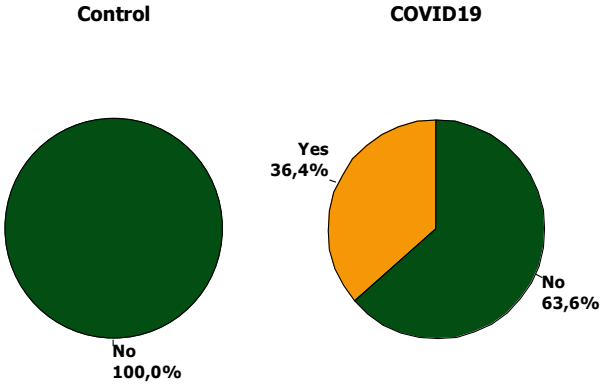

Fig. 7. The overall prevalence of 'Emergency of defecation' between the COVID-19 group and their sex-matched controls

DISCUSSION

Our present results are confirming that COVID-19 patients could exhibit GI disturbances. Moreover, we observed that these GI impairments could be evaluated by a VAS-IBS scale, thus leading to the conclusion that in this context the GI impairments could resemble the IBS gastrointestinal symptoms. Therefore, the data show that COVID-19 patients significantly frequently exhibit diarrhea, constipation, abdominal pain, bloating, and vomit-

ing. In this context, Chaoqun *et al.*, (18), Hormati *et al.*, (19), and Wang *et al.*, (20) also showed the mentioned GI impairments were present in COVID-19 patients. Congruent, they also showed that abdominal pain, vomiting, bloating, and nausea are prevalent among these individuals.

Having as purpose to determine the virological, clinical and epidemiological features of SARS-CoV-2-infected patients, Jin *et al.*, (21) enrolled in their study a cohort consisting of six hundred and fifty-one patients. From the total number, approximately 11.4% (n = 74) admitted exhibit at least one GI symptom, identical to those reported by us. Lin *et al.*, (22) revealed that 58 (61.1%) out of 95 patients had GI deficiencies, the most frequent being diarrhea. They were able to identify the niches where this virus resides within the human organism, viral signatures in stool samples being present starting from day seven, up to twelve days (23-26).

From a group of 40 patients initially included in the study, 45% of all patients did not have suffered from any gastrointestinal symptom according to the results of Effenberger *et al.*, (27) Moreover, in 55% of cases GI symptoms have ceased after only a couple of days, but in nine of them persisted for a longer time. In this context, such similar findings together with our results suggest that a correlation between SARS-CoV-2's pathogenesis and the incidence of the GI deficiencies.

Continuing with this concept, it has been hypothesized that SARS-CoV-2 can survive within its host until a certain temperature after host's death (28), and even after clearance of the respiratory tract (29). On the other hand, viral signatures can be identified after approximately four weeks since admission (25).

Particular cases have been also reported in the literature. We identified one case report in which the authors discussed the case of an 80-year-old woman previously diagnosed with left-sided ulcerative colitis (UC) that died days before the outbreak started. She developed pneumonia associated with the infection with SARS-CoV-2 and during the fourth day it passed away (30). There is certain controversy around this topic because recently was discussed about the low risk of mortality rate in patients with inflammatory bowel disease (IBD) (31). There are also strong chances for developing autoimmune disorders such as Reiter's syndrome (32), being even hypothesized that this pathogen could be associated with the Guillain-Barré syndrome (33).

Moreover, this preliminary paper of ours could open the discussion on the obvious connections that might exist between the digestive and gastrointestinal component that is associated with the neuropsychiatric one (34, 35), considering the latest expertise of our group in this area (36-40), as well as the social implications in this context (41, 42), and of course the neurological and psychiatric manifestations related to COVID-19 (43-49). In this way, our group is further working right now on establishing the interactions between digestive and neuropsychiatric manifestations, in the complex COVID-19 pathological context.

CONCLUSIONS

Based on the aforementioned, our results clearly demonstrated that VAS-IBS questionnaire is a reliable tool to measure the severity of GI deficiencies in both

healthy and infected individuals. Moreover, this could suggest some novel insights regarding the underlying mechanism between COVID-19 and gut that now are crucial.

It is possible, on one hand, that some specific symptoms of IBS may be present in patients with COVID-19 in a conjunctural manner, whether it is to think about the quality of life or the emotional status. An under-evaluated link is the psychological impact that isolation, quarantine and hospitalization have on patients diagnosed with COVID-19 and the risk towards various neurological disorders.

ACKNOWLEDGMENTS. We would like to give special thanks to Professor Marietta Bengtsson from the University of Malmo, Sweden, for granting the permission to use the VAS-IBS scale.

CONFLICT OF INTEREST.

THE IMPLICATIONS OF INFLAMMATORY MARKERS AND LACTIC ACID IN ELDERLY PATIENTS WITH DEPRESSION (Abstract): Depression can be defined as the nosological entity that includes both mood swings and psychotic symptoms, accompanied by emotional changes and a significant decrease in cognitive and psychomotor functions. The hypothesis of membrane theories of depression and its pathophysiology is based on the existence of a change in the structure and physiology of the cell membrane regarding receivers and loci for different substances. Tissue lesions are present in the cerebral atherosclerotic process with manifestations in the arterial endothelium whose dysfunction occurs as a result of a chronic inflammatory process caused by the atherosclerotic plaque. **Material and methods:** The study took place between January and June 2015 at the 5th Medical Clinic of the "CFR" Clinical Hospital in Iași, Romania. The study was conducted on 98 patients divided into two groups according to cardiovascular disease and the presence of depression and cognitive deficit**.** The objective of the study is the evaluation of depression and anxiety in correlation with the inflammatory profile in patients with cardiovascular disease. **Results:** Statistical analysis of intergroup differences for inflammatory markers, lactic acid and markers of subclinical atherosclerosis revealed that there are statistically significant differences between the average of said parameters between the two study groups. **Conclusions:** In the control group (patients with only cardiovascular disease) there were statistically significant correlations between the inflammatory markers, subclinical atherosclerosis, lactic acid and the assessment of depression and cognitive deficit. **Keywords:** DEPRESSION, ANXIETY, INFLAMMATORY MARKERS, LACTIC ACID, SUBCLINICAL ATHERO-SCLEROSIS.

Depression is considered an independent cardiovascular risk factor for future coronary events in healthy subjects. The most studied association between anxiety symptoms and somatic symptoms is that of cardiovascular and respiratory diseases, which can trigger states of fear, anxiety, and anxious waiting. Anxiety caused by the

presence of severe heart disease is worsened by the awareness of cardiac dysfunctions (tachycardia, extrasystoles, arrhythmias), the occurrence of retrosternal pain, breathing difficulties or fatigue (1-4).

A study carried out by the University of Iowa showed statistically significant correlations of lactic acid levels with anxiety levels. The results of the Iowa study suggest that one of the triggers for spontaneous panic attacks in patients with anxiety disorders could be increased lactic acid concentration in acid-sensitive fear circuits. Determination of lactic acid in the blood is known to play an important role in monitoring patients with tissue hypoxia (5). Clinical studies show the importance of determining blood lactate especially in patients in critical condition or at high risk of decompensation. The role of lactate in biochemistry and physiology is confirmed by clinical and experimental research. Clinically, the increase of blood level lactate indicates an exacerbation of tissue disorders and an increased risk of death. However, research has shown that the concentration of lactic acid <1 mmol/L has diagnostic significance. Lactic acid is one of the intermediates of glucose metabolism, a process that occurs in all organs and systems (6, 7). The largest production of lactate is in erythrocytes and muscle tissue, from which it enters the blood. Lactic acid is used in cardiomyocytes and hepatocytes in energy metabolism and glucose synthesis (gluconeogenesis). Sufficient perfusion of tissues with oxygen reduces glucose to CO_2 and H_2O with energy release.

Insufficient perfusion of oxygen in the tissues can greatly accelerate anaerobic processes, which are known to be accompanied by the production of a much higher amount of lactic acid, which accumulates in the tissues and blood with the development of lactic acidosis. One such disorder that the elderly is more prone to and can lead to lactic acidosis is chronic venous disease (8). The determination of this metabolic product is a necessary method of monitoring patients with hypoxia and whose clinical condition changes rapidly (9). The concentration of lactic acid, according to the data of different studies, should be in the range of1.8-2.0/1.85-2.2/2.2-2.7 mmol/L.

The increase of lactic acid production in the myocyte leads to the decrease of the intracellular pH and implicitly the inhibition of glycolysis, the use of fatty acids and the overall process of protein synthesis, which ultimately leads to the necrosis of cardiomyocytes. In ischemia, it is known that increased lactic acid levels are one of the major causes of angina (10). Another effect high lactic acid can have on the body is the influence on bone density over time and future prosthetic interventions, which may, in turn, exacerbate the overall functional status of elderly patients, thus leading to depression (11).

MATERIAL AND METHODS

The study took place between January and June 2015 at the 5th Medical Clinic of the "CFR" University Clinical Hospital in Iasi, Romania. The study was conducted on a number of 98 patients divided into two groups according to cardiovascular disease and the presence of depression and cognitive deficit.

- Group I: Normal cognition, which includes subjects with cardiovascular disease and normal psychological ageing without cognitive impairment or clinical depression - control group.
- Group II: Normal cognition, which in-

cludes subjects with cardiovascular disease and normal psychological ageing without cognitive impairment but with clinical depression.

Exclusion criteria included: history of substance use disorders, cognitive impairment, psychotic disorders, history of allergy to antihypertensive drugs, heart failure class III or IV NYHA, hepatitis B, C and/or HIV positive.

The aim of the study. To investigate the interaction of fibrinogen, C-reactive protein (CRP) as an inflammatory marker and lactic acid as a factor relating to depressive disorders. The study aims to explore whether determining the values of C-reactive protein, lactic acid and subclinical atherosclerosis have a predictive role in the occurrence of mixed depression/anxiety events in coronary patients.

The objectives of the study. Assessment of depression and anxiety in correlation with the inflammatory profile in patients with cardiovascular disease. Assessment of the clinical and biological correlations of depression-anxiety- subclinical atherosclerosis in the geriatric patient.

RESULTS

Group I

Assessment of anxiety and depression

The average value of the Hamilton scale scores for depression was 2.43 points, 85% of the patients had the values of the Hamilton scale scores for depression within the range of 0-5 points (fig. 1).

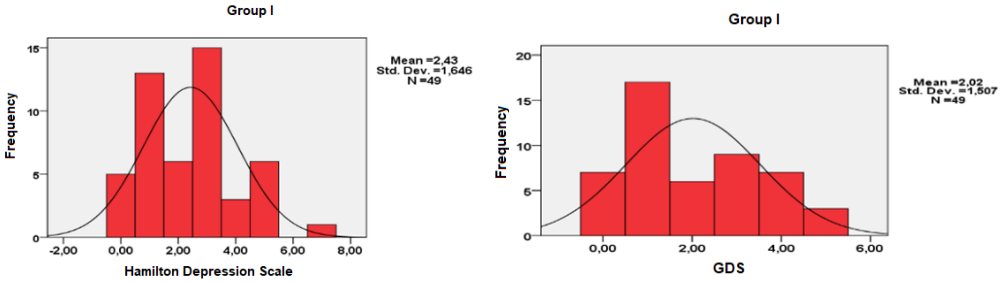

Fig. 1. Histogram of the distribution of the average values of the Hamilton scale in group I

The average value of the Geriatric Depression Scale scores was 2.02 points in group I. (fig. 1). Statistical analysis of the differences in the mean scales for assessing depression for the patients in group I by gender did not reveal statistically significant differences for both scales used (tab. I).

The average value of the Geriatric Depression Scale scores was 22.46 points, 69% of the patients had the values of the Geriatric Depression Scale scores within the range of 25-30 points (fig. 2). The average value of the Hamilton scale scores for depression was 24.06 points, 87% of the patients had the values of the Hamilton scale scores for depression within the range of 22-24 points (fig. 2).

TABLE I

Mann-Whitney test in group I

test	HDRS	GDRS
Mann-Whitney U	237,000	265,000
Wilcoxon W	562,000	590,000
Z	- 1.274	-0.707
p	0.49	-0.28

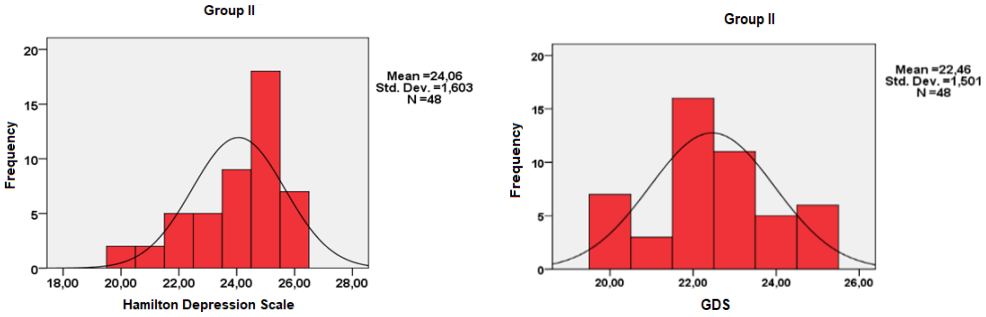

Fig. 2. Histogram of the distribution of the average values of the MMSE scores in group II.

Statistical analysis of the differences in the mean scales for the depression assessment for the patients in group II by gender did not reveal any statistically significant differences for both scales used (tab. II).

TABLE II

Mann-Whitney test in group II

test	HDRS	GDRS
Mann-Whitney U	267,500	158,500
Wilcoxon W	543,500	483,500
Z	-0.419	- 2.756
p	0.66	-0.64

Hamilton Anxiety Scale

The mean value of the Hamilton Anxiety Scale was 8.31 points, 56% of the patients had the values of the Hamilton Anxiety Scale scores in the range of 4-6 points (fig. 3).

Statistical analysis of the differences in the means of the Hamilton Anxiety Scale for the patients in Group I by gender did not show statistically significant differences (U=298.0; z=-0.041; p =0.96).

The mean value of the Hamilton Anxiety Scale scores was 18.02 points, 81% of the patients had the values of the Hamilton Anxiety Scale scores within the range of 17-20 points.

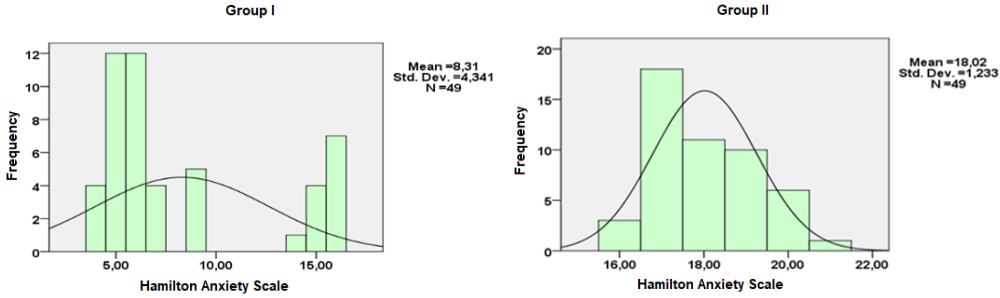

Fig. 3. Histogram of the distribution of the mean values of the Hamilton Scale for Anxiety in Group I and Group II

Statistical analysis of the differences in the means of the Hamilton Anxiety Scale for the patients in Group II by gender showed no statistically significant differences (U=287.0; z=-0.49; p =0.80).

Inflammatory markers

The mean fibrinogen value was close to 2.57 mg/dL, 59% of patients had mean fi-

brinogen values in the range of 2.5-3.0 mg/dL. The mean CRP value was 3.46 mg/dL, 89% of patients had mean CRP values in the range of 3.0-4.0 mg/dL (fig. 4).

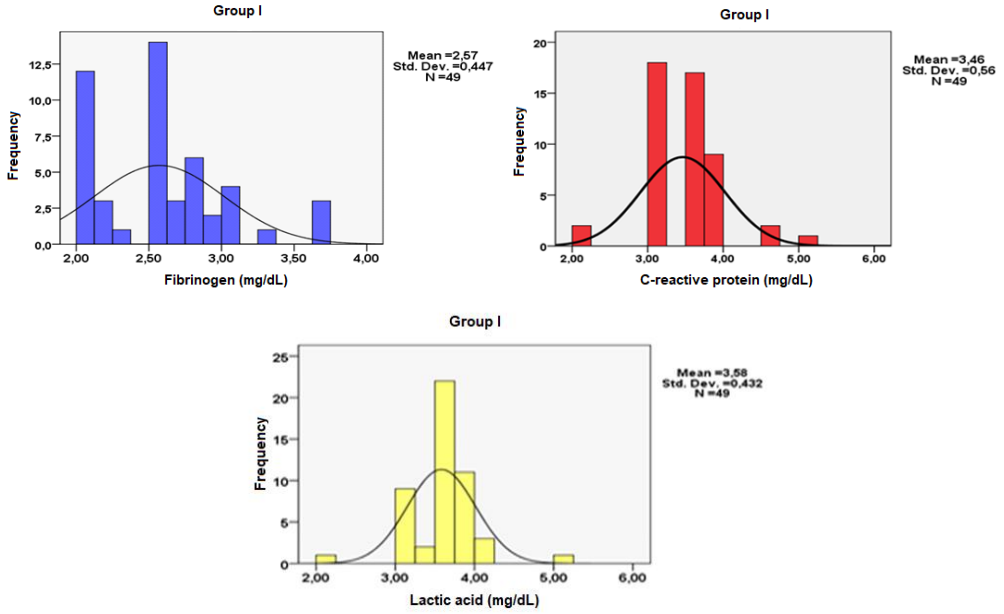

Fig. 4. Histogram of the distribution of fibrinogen means values in group I.

The mean lactic acid value was 3,68 mg/dL, 96% of patients had mean lactic acid values in the range of 3-4 mg/dL (fig. 4).

Group II

The mean fibrinogen value was 2.88 mg/dL, 67% of patients had the mean fibrinogen value in the range of 2.5-2.9 mg/dL. The mean CRP value was 3.86 mg/dL, 61% of patients had mean CRP values in the range of 3.3-3.8 mg/dL. The mean lactic acid value was 4.65 mg/dL, 69% of patients had mean lactic acid values in the range of 4.5-4.8 mg/dL (fig. 5).

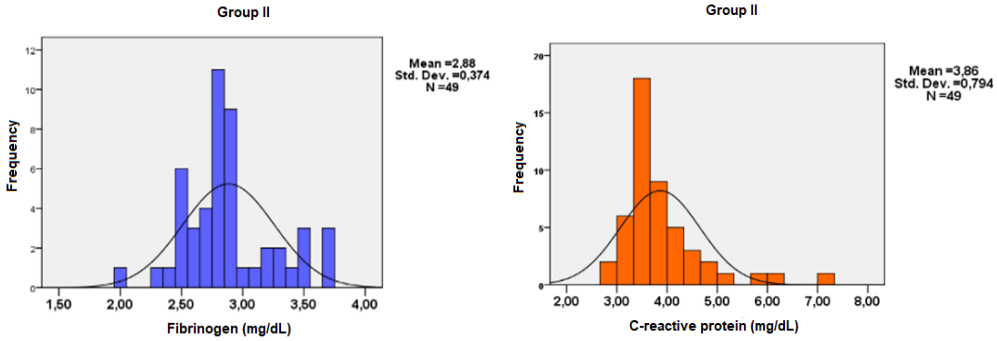

Fig. 5. Histogram of the distribution of the average fibrinogen values in group II

The markers of subclinical atherosclerosis

The literature suggests that the identification of subclinical atherosclerosis by noninvasive techniques such as ankle-brachial index (ABI), carotid intimal thickness (CIT), cardiac calcium scoring, arterial stiffness index, in asymptomatic individuals could be a useful method for both long-term predictions, where there is still no prediction tool, as well as for improving short-term prediction.

Subclinical atherosclerosis is strongly correlated with future cardiovascular events, independent of conventional cardiovascular risk factors. Its detection would be important because it would indicate an extremely aggressive intervention on risk factors, both by optimizing lifestyle and statin therapy, independent of the overall cardiovascular risk, highlighting subclinical atherosclerosis in a vascular territory being constantly accompanied by other locations.

The mean value of the ABI scores was 0.77. 94% of the patients had the ABI values in the range of 0.7-0.8 (fig. 6).

The mean value of the CIT scores was close between men (0.74±0.71 SD) and women (0.74±0.72 SD) of group I. (0.74±0.71 SD). 88% of the patients had the CIT values in the range of 0.7-0.8 (fig. 6).

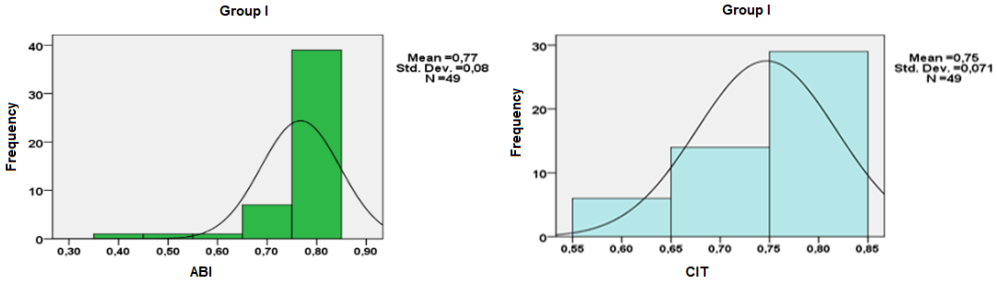

Fig. 6. Histogram of the distribution of the mean values of ABI, CIT in group I.

The mean value of the ABI scores was 0.81, 94% of the patients had the ABI values in the range of 0.7-0.8 (fig. 7).

The mean value of the CIT scores was 0.80, 88% of the patients had the CIT values in the range of 0.8-0.9 (fig. 7).

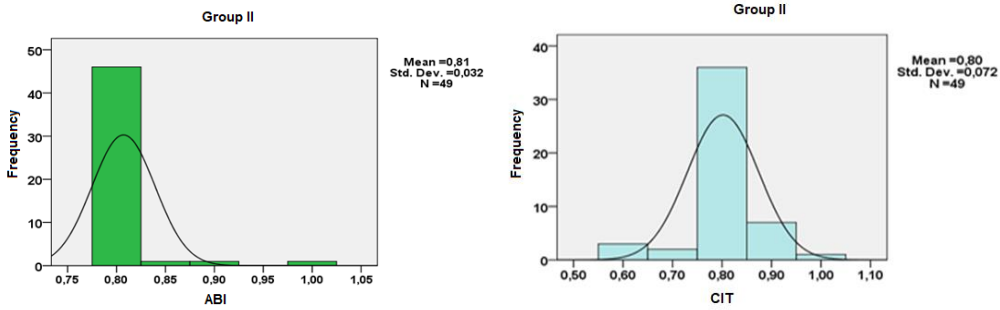

Fig. 7. Histogram of the distribution of the mean values of ABI, CIT in group II

Correlation analysis

The study of the correlations between the markers of subclinical atherosclerosis and cognitive status, depression, and anxiety in the patients of group I highlighted the following significant correlations:

- *Fibrinogen* was significantly correlated with lactic acid (p =0357. r=0.012), Hamilton Anxiety Scale (p=0.283. r=0.049), Hamilton Depression Scale (p=0.386. r=0.006), Geriatric Depression Scale (p=0.309. r=0.031), ABI (p=0.529. r ≤ 0.001), GIN (p =0.623. r ≤0.001).

- *CRP* was significantly correlated with lactic acid (p =-0.05. r ≤0.001), Hamilton Anxiety Scale (p =0.492. r ≤0.001). Hamilton Depression Scale (p =0.49. r ≤0.001).

- *Lactic acid* was significantly correlated with CRP (p =-0.5. r ≤0.001), fibrinogen (p = 0.357. r=0.012), Hamilton Depression Scale (p =0.792. r ≤0.001), Hamilton Anxiety Scale (p = 0.439. r ≤0.001), Geriatric Depression Scale (p =0.372. r=0.008), CIT (p =0.368. r=0.009).

The study of the correlations between the markers of subclinical atherosclerosis and cognitive status. depression and anxiety in the patients of group II highlighted the following significant correlations:

- *Fibrinogen* was significantly correlated with MMSE (p =0.521. r ≤0.001), Hamilton Anxiety Scale (p =0.286. r=0.046), Hamilton Depression Scale (p =0.357. r=0.012), CRP (p =-0.49. r ≤0.001)

- *CRP* was significantly correlated with lactic acid (p =-0.48. r ≤0.001), MMSE (p = 0.75. r ≤0.001), Hamilton Anxiety Scale (p =-0.349. r=0.014), Hamilton Depression Scale (p =-0.48. r ≤0.001).

- *Lactic Acid* was significantly correlated with CRP (p =-0.48. r ≤0.001), MMSE (p =-0.45. r=0.001), Hamilton Anxiety Scale (p =0.595. r ≤0.001), Hamilton Depression Scale (p =0.44. r≤0.001), Geriatric Depression Scale (p =0.296. r=0.039), CIT (p =-0.28. r=0.046).

DISCUSSION

In most degenerative processes specific to cardiovascular ageing, but also in cardiovascular diseases, adaptive structural and functional tissue changes occur at both macrovascular and microvascular levels (12). The significant increase in the carotid intimal thickness and the rarefaction of the conjunctival microcirculation (a phenomenon characterized by a decreased density of arterioles and capillaries) are examples of such changes. The carotid intimal thickness is used as a predictive index of future cardiovascular and cerebrovascular events (13). The association of the change of the carotid intimal thickness with cerebrovascular diseases, symptomatic strokes but also with cerebral lacunes was confirmed by clinical studies. An association between asymmetric cerebrovascular pathology and left cerebral pathology was also observed. High blood pressure has also been described as an independent risk factor, possibly a predictor of cerebral lacunes and cerebral white matter lesions, which in turn, are predictive factors for the development of cognitive impairments over time (14).

Oxidative stress amplifies the movement of proinflammatory cells, increases the expression of some adhesion molecules to the surface of endothelial cells and causes lipid oxidation at the blood-brain barrier (10, 15-17). Similar to our results, it was found that erythrocyte sedimentation rate and total serum proteins could be used as a predictive biomarker for high or low levels of anxiety in patients with chronic obstructive pulmonary disease, indicating that routine blood panels could serve as objective indicators of psychiatric symptoms in chronically ill patients (18).

The pathophysiology of Alzheimer's disease is described microscopically by the presence of senile plaques and neurofibrillary tangles along with the decrease in the

number of synapses and macroscopically by cerebral atrophy. Tests on oxidative damage were performed in the brains of patients with Alzheimer's disease by post-mortem harvesting. The main element of senile plaques is β-amyloid. Although this is not a defining characteristic, it is associated with Alzheimer's disease and old age. The relation of the β-amyloid with oxidative stress is controversial. Some studies give it as a source of free radicals and give it a prooxidative role (19) and as an inducer of neuronal apoptosis.

The boundaries between degenerative dementia and vascular dementia are now less clear and both types include several risk factors, clinical and/or pathological features of the same kind. Cerebrovascular disease is thought to play an important role in the presence and severity of Alzheimer's disease (9). A meta-analysis of randomized controlled research shows that cholinesterase inhibitors used in the treatment of degenerative dementia led to only minor cognitive improvements, causing uncertain clinical significance in patients with early to moderate vascular dementia.

Differences in the calibration of depression, research design and presentation of results, determined the heterogeneous nature of the findings. Risk factors for post-stroke dementia are female gender, physical disability, a history of depression and a history of mental and emotional vulnerability after stroke. The diagnosis of post-stroke depression can be masked by symptoms such as aphasia, agnosia, apraxia, and memory disorders. Although there is encouraging data on the prophylactic use of antidepressants in stroke patients, there is still insufficient evidence to implement this approach in therapeutic protocols after a stroke (1, 20).

Territorial increase of cardiac noradrenergic activity may be the condition by which desipramine (a possible noradrenaline reuptake inhibitor) leads to increased blood pressure values (1).

Another theory shows that the central serotonin system could be responsible for regulating blood pressure. Inhibition of serotonin reuptake causes a cascade of changes in central neurotransmission, accentuating the tone of the vegetative nervous system. Fluoxetine and sertraline lead to increasing and altered blood pressure in patients with orthostatic hypotension and can be used to treat recurrences of hypotension.

CONCLUSIONS

Within the control group (patients with only cardiovascular disease) there were significant statistical correlations between the inflammatory markers, subclinical atherosclerosis, lactic acid and the assessment of depression.

There were no statistically significant differences between the means of the studied parameter values based on the gender of the patient in the overall study group.

Inflammatory markers were significantly correlated with the scores obtained when assessing depression and anxiety.

Lactic acid as a substrate for anxiety has been correlated with depression.

ABI and CIT as indirect determinants of subclinical atherosclerosis were statistically significantly correlated with depression.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

SPECTRUM OF PRECIPITATING FACTORS OF HEPATIC ENCEPHALOPATHY IN PATIENTS WITH LIVER CIRRHOSIS (Abstract): Hepatic encephalopathy (HE) is one of the most frequent and debilitating complications of liver cirrhosis. Identification and correction of precipitation factors are mandatory to ensure a favorable outcome. **Material and methods:** We performed a retrospective descriptive study in cirrhotic patients with HE hospitalized during one pandemic year in a tertiary care referral center. Demographic, clinical and biological parameters, as well as the etiology of the liver cirrhosis were recorded. Precipitating factors were identified, and their prevalence was calculated, overall and according to the two main etiologies of cirrhosis. **Results:** Prevalence of HE was 71%. The most frequent overall precipitating factors were infections (43.7%), gastrointestinal bleeding (31.6%), renal failure (28.9%) and dyselectrolytemia (26.2%). According to cirrhosis etiology, significant higher frequencies of sepsis and non-adherence to therapy were found in patients with alcoholic cirrhosis compared to those with virus-related cirrhosis (6.1% *vs.* 0.8%, p=0.012, and 15.5% *vs.* 8.3%, p=0.026, respectively), while prevalence of hepatocellular carcinoma as causal factor of HE was significantly higher in virus-related cirrhotic patients compared to alcoholic cirrhosis (14.3% and 6.4%, respectively, p=0.004). Non-variceal bleeding was recorded especially in alcoholic patients. About half of patients had one single precipitating factor, nearly 40% had multiple factors, while for 11% no factor was identified. **Conclusions:** HE has high prevalence in hospitalized cirrhotic patients. The most common precipitating factors are infections, gastrointestinal bleeding, renal disfunction and electrolyte imbalances. Particular risk factors were found in relation to the etiology of cirrhosis, data that could help apply a tailored, individually-adapted preventive strategy. **Keywords:** HEPATIC ENCEPHALO-PATHY, LIVER CIRRHOSIS, PRECIPITATING FACTORS, ALCOHOLIC CRIRRHOSIS, VIRUS-RELATED CIRRHOSIS.

Hepatic encephalopathy (HE) is one of the most frequent complications of liver cirrhosis. It negatively affects patients' quality of life and has unfavorable short- and long-term impact on their clinical outcome. Moreover, because of complex therapeutic measures and frequent hospitalizations, HE may associate a significant burden in term of healthcare resources.

The frequency of HE is related to the

functional status of the liver and to the degree of portal hypertension, with direct consequence on the portosystemic shunt formation. According to the clinical presentation, HE is classified in covert HE, which includes minimal HE (detectable only by special psychometric tests) and grade 1 HE, and overt HE, which includes grade 2-4 HE according to West-Haven criteria (1). In terms of prevalence, 10-15% of patients present overt HE at the moment of the diagnosis of cirrhosis (2), and 16-21% of patients with decompensated cirrhosis associate overt HE (3). During the first 5 years after the diagnosis of cirrhosis, the risk for HE is up to 25% (4), while in evolution, up to 40% of cirrhotic patients will present with HE, mostly in a recurrent manner (5).

There are multiple well-defined precipitating factors, which can cause, by various mechanisms, episodic or recurrent episodes of HE. Identification of precipitating factor by thorough work-up is mandatory in order to apply the optimal management strategy. The recognition and, subsequently, the correction of the precipitating factor is the first step in treating HE episodes. About 90% of patients with HE requires only the correction of the precipitating factor as therapeutic approach (6), therefore identifying and controlling precipitating factors is essential.

Precipitating factors are represented mainly by infections, gastrointestinal bleeding, constipation, electrolyte disorders, renal disfunction, hepatotoxic agents, and others. Awareness and promptly recognition definitely influence favorably the individual therapeutic approach and may warrant therapeutic success. As there is a 40% cumulative risk of another recurrence during the 6 months following the previous episode of, HE (7), tight surveillance and, ideally, avoidance of precipitating factors could represent an effective prophylactic measure.

The aim of our study was to assess the prevalence of various precipitating factors for HE in patients with liver cirrhosis, and to identify particular precipitating factors according to the etiological profile of cirrhosis, data that could help apply a tailored, individually-adapted preventive strategy.

MATERIAL AND METHODS

We performed a retrospective, descriptive study, including all the patients with HE and liver cirrhosis, hospitalized during the COVID-19 pandemic year (April 1st, 2020 - March 31st, 2021) in the Institute of Gastroenterology and Hepatology, "Sf. Spiridon" County Clinical Emergency Hospital Iasi, a tertiary referral care center in North-East Romania. Among all 743 cirrhotic patients hospitalized during this period, 526 fulfilled the West Haven criteria for HE. Demographic, clinical and biological characteristics of the patients, as well as the etiology of the liver cirrhosis were recorded. Precipitating factors were identified, and their prevalence was calculated, both overall and according to the main etiologies of cirrhosis.

Statistical analysis

Analysis was performed using *SPSS version 24.0*. Categorical data was described using frequencies and percentages. Continuous data were expressed as means and standard deviation (SD). Results were considered with statistical signification for a p-value <0.05.

RESULTS

Overall prevalence of HE

Out of all 743 cirrhotic patients hospi-

talized during one pandemic year in our care center, 526 patients with HE was identified, resulting an overall HE prevalence of 71%.

Patients' characteristics

Demographic characteristics of the patients, etiology, Child-Pugh and MELD scores of liver cirrhosis, and grades of HE according to West-Haven criteria are presented in the first table. The most common causes for cirrhosis were alcohol, with almost three quarters of cases (393 patients, 74.7%) and viral, with less than a quarter (118 patients, 22.4%), while other causes were much less frequent (metabolic 1.5%, primary biliary cirrhosis 0.8%, Wilson disease 0.6%). 99% of the patients had decompensated cirrhosis, corresponding to class Child-Pugh B and C. Mean values of MELD scores were above the cut-off for liver transplantation. The most patients (40.3%) had grade 2 HE according to West-Haven criteria, followed by grade 1 (30.8%), and grade 3 (19.4%); 9.5% of patients had hepatic coma, corresponding to grade 4 HE.

TABLE I

Characteristics of the study patients

Parameters	Patients, n=526
Age, mean ± SD	57.37 ± 11.5
Gender ratio, n (%)	
Men	318 (60.5)
Women	208 (39.5)
Place of origin, n (%)	
Urban area	243 (46.2)
Rural area	283 (53.8)
Etiology of cirrhosis, n (%)	
Alcoholic	393 (74.7)
Virus-related	118 (22.4)
Hepatitis C virus infection	49 (9.3)
Hepatitis B and D virus infection	32 (6.1)
Hepatitis B virus infection	28 (5.3)
Hepatitis B and C virus infection	9 (1.7)

4	50 (9.5)

Precipitating factors of HE

Type and overall frequency of each precipitating factor are presented in the second table. As nitrogen overload conditions, we recorded especially gastrointestinal bleeding (the most common type being variceal bleeding) with a prevalence of 31.6%, renal disfunction, with a prevalence of 28.9%, and constipation, prevalence 9.9%. Dyselectrolytemia, as meaningful metabolic alteration, had a prevalence of 26.2%. The systemic stress situations were dominated by infections (the highest prevalence, 43.7%), the most common being spontaneous bacterial peritonitis, urinary tract infection, *Clostridioides difficile* colitis, COVID-19, other respiratory tract infections, and cellulitis. Active alcohol consumption was recorded in 12.4% of cases. Patients' non-adherence to treatment was responsible for HE in 13.7% of cases. Other precipitating factors were hepatocellular carcinoma (HCC), TIPS and surgery. In nearly half of patients, one single factor was incriminated, while in 39.3% of cases, multiple factors were recorded. In 11.6% of cases, no precipitating factor was identified.

TABLE II

Precipitating factors of HE in the study group

Precipitating factors		Patients, n (%)
Nitrogen overload	**Gastrointestinal bleeding**	**166 (31.6)**
	Variceal bleeding	129 (23)
	Non-variceal bleeding	37 (7)
	Constipation	52 (9.9)
	Renal disfunction	**152 (28.9)**
Metabolic alteration	**Dyselectrolytemia**	**138 (26.2)**
Systemic stress	**Infections**	**230 (43.7)**
	Spontaneous bacterial peritonitis	73 (13.9)
	Urinary tract infection	41 (7.8)
	Clostridioides difficile colitis	34 (6.5)
	COVID-19	31 (5.9)
	Sepsis	25 (4.8)
	Respiratory tract infection (other than COVID-19)	21 (4)
	Cellulitis	5 (1)
	Surgery	8 (1.5)
Hepatotoxic agents	Active alcohol consumption	65 (12.4)
Others	HCC	44 (8.4)

DISCUSSION

HE is a frequent complication of liver cirrhosis, and its occurrence is usually determined by another concomitant pathological condition or acute event which act as trigger factors. Mechanisms involved are complex, hyperammonemia being the leading path towards the alteration of the brain functioning. The spectrum of the clinical manifestations of HE is heterogenous, and the severity of this complication can vary from mild, subtle symptoms to life-threatening conditions as hepatic coma. Depending on the methods of assessment and the type of study population, prevalence of HE varies. While among all cirrhotic patients, HE prevalence is usually up to 20% (3), some studies so far showed more increased prevalence in hospitalized cirrhotic patients (8). However, patients with advanced, decompensated and/or complicated cirrhosis are the most prone to

develop HE. This explains why our analysis showed a much higher prevalence (71%); during pandemic, the hospitalized population consisted almost exclusively in severe cirrhotic patients, usually associating serious specific complications. Current classification distinguish covert HE (minimal HE and grade I according to West Haven criteria) from overt HE (grades II-IV according to West Haven criteria). In our study, 162 patients (31%) had covert HE (grade I), while the majority (364 patients, 69%) presented overt HE. The majority of cirrhotic patients which present with HE manifestations need hospitalization. Treatment may involve advanced support measures, and furthermore, identification and correction of precipitating factors is mandatory. Precipitating factors are often multiple, either concomitant or consecutive to each other, because one complication of cirrhosis frequently causes another.

In our study, infections were the most frequent precipitating factors (43.7%), the commonest being spontaneous bacterial peritonitis, followed by urinary tract infections, *Clostridioides difficile* colitis, COVID-19 pneumonia, sepsis, respiratory infections (other than SARS-CoV-2) and cellulitis. Universal data so far show that infections are recognized among the main precipitating factors for both episodic and recurrent HE. There seem to be, however, certain differences according to the region reported: infections appear as the most frequent precipitating factors (responsible for up to 65% of cases of HE) in the developing countries (8, 9, 10) while studies from western world report infections with much lower frequency as precipitating factors for HE (11, 12). Adherence, good nutritional and immunologic condition and functionality of health system might explain lower frequency of infections. In relation to cirrhosis etiology, we found a significant higher frequency of sepsis as trigger factor for HE in patients with alcoholic cirrhosis compared to those with virus-related cirrhosis (6.1% and 0.8%, respectively, p=0.012). Alcoholic patients have poorer immune status and generally negative health outcome (13), which could explain why they are the most exposed to septic complications. Respiratory tract infections were found to be more frequent in alcohol-related cirrhosis, reflecting the higher risk of pulmonary complications in this group of patients, involving issues as self-neglecting or aspiration.

The second most frequent precipitating factor of HE was gastrointestinal bleeding. Nearly one third of all patients (31.6%) presented bleeding as major risk factor; among them, variceal bleeding was more prevalent, with approximately three quarters of cases, while the rest had non-variceal bleeding. Cirrhotic patients usually bleed from esophageal or gastric varices (60-65%) (14), but non-variceal sources are also recorded (mainly peptic ulcers, erosive gastritis, Mallory-Weiss syndrome) (15). In our study, non-variceal bleeding tended to be more frequent in patients with alcoholic cirrhosis compared to patients with virus-related cirrhosis. Indeed, alcohol consumption can directly cause hemorrhagic upper gastrointestinal lesions, such as acute erosive gastritis, esophageal ulcers, Mallory-Weiss syndrome, and, in the same time, it has been associated *per se* with an increased risk of upper gastrointestinal bleeding, especially secondary to peptic ulcer (16,17). While variceal bleeding is classi-

cally seen as the most dramatical and potentially lethal complication, with 6-week mortality up to 20% (18), the non-variceal bleeding in patients with cirrhosis is as well of upmost importance, since clinical outcomes are more severely influenced, in terms of morbidity and even mortality, compared to non-cirrhotic patients (19, 20). Rapid adapted treatment is mandatory in all cases of gastrointestinal bleeding, to avoid high rate of mortality.

Renal failure was the third most common precipitating factor (28.9% of all patients). There are many mechanisms of renal impairment in liver cirrhosis, leading directly to nitrogen overload and consequent brain disfunction. According to etiology of cirrhosis, renal disfunction was more frequent (34.6%) in virus-related cirrhosis (the second most common, after infections and before gastrointestinal bleeding). The spectrum of renal impairment in patients with liver cirrhosis covers several main entities, as acute kidney injury with or without features of hepatorenal syndrome, acute kidney disease and chronic kidney disease (21). In our analysis, virus-related cirrhosis was found to be more exposed to renal complications, probably because both hepatitis B virus infection and hepatitis C were reported as causes of chronic renal disease, mostly due to membranous glomerulonephritis (22), or cryoglobulinemia and focal segmental glomerulosclerosis, respectively (23).

Dyselectrolytemia was the fourth most frequent precipitating factor (26.2%), with similar prevalence in relation to the etiology of cirrhosis. Hyponatremia, hypokalemia or hyperkalemia and alkalosis are the main electrolyte imbalances that can trigger HE, independently or associated to renal disfunction (24). Diuretics and consequent hypovolemia or dehydration are risk factors for both electrolyte disorders and acute renal failure, and tight surveillance is mandatory to avoid harmful overlap.

Active alcohol consumption was unfortunately frequent as trigger factor for HE among patients with alcoholic cirrhosis (16.5%). This underlines the urge need to actively combat alcohol consumption, which is not only a main cause for chronic liver disease, but also a factor for further progression and recurrent complications. Conversely, in the viral cirrhosis group, no cases of active alcohol consumption were identified. As listing for liver transplantation requires at least 6 months abstinence, the significance of the matter is tremendous.

A particular issue appears to be non-adherence to therapy, more significant in patients with alcoholic cirrhosis compared to viral cirrhosis (15.5% and 8.3%, respectively, p=0.026). Neglecting the treatment of a potential precipitating factor or lack of proper prophylaxis measures put the patients at risk for developing HE. Again, more efforts for a better compliance seem to be needed in alcoholic patients.

An important severe, potentially fatal complication of liver cirrhosis is hepatocellular carcinoma (HCC), which develops in one third of cirrhotic patients overall during their lifetime, with annual risk of up to 8% (25). HE may be induced by hepatic failure associated to HCC. All patients with liver cirrhosis, regardless of etiology, are at risk for HCC, but hepatitis B and C virus-related cirrhosis are particularly exposed. In our analysis, prevalence of HCC as causal factor of HE was significantly higher in virus-related cirrhotic patients compared to alcoholic cirrhosis (14.3% and

6.4%, respectively, p=0.004). Surveillance is mandatory in all cirrhotic patients, to allow diagnosis in curable stages.

Seen as a relatively common precipitant factor of HE, especially for recurrent episodes (26), constipation was found to be in our study responsible for less than 10% of cases. Our study included only hospitalized patients during pandemic, while patients with non-severe forms of HE, having constipation as trigger factor, were managed as outpatients.

Surgery is a stress condition that may decompensate and induce HE (9). A few patients in our study (1.5%) had surgery as responsible factor for HE, as interventions in cirrhotic patients should be reserved only for critical and life-menacing situations, especially if already decompensated.

A less frequent but equally important causal factor for HE was trans jugular intrahepatic portosystemic shunt (TIPS). TIPS may complicate with HE in various proportions (18-50%), depending mostly on the type of stent (diameter, bare or covered) (27). In our analysis, four cirrhotic patients presented with HE as a consequence of the TIPS. Time of insertion and the type of TIPS, used as treatment of recurrent bleeding or refractory ascites, must be very well weighted, in order to assure a favorable risk-benefit ratio.

Identifying and correction of precipitating factors are essential, as in many cases, up to 90%, controlling the cause assures the effective treatment of HE episode (6). However, some cases can be challenging, when no factor is finally found or when, by contrary, multiple factors overlap. We found a relatively low proportion (11%) of patients without identifiable precipitating factor. Exhaustive work-up must be always performed in order to find the potential trigger, but clinicians must be aware of the existence of the so-called "nonprecipitated" HE, mainly caused by spontaneous portosystemic shunts (28). HE may have more than one precipitant factor, situation found in our study in a high proportion (39%), similar results being reported by other several studies (29,30,31). Independent or related to each other, various concomitant events or complications of cirrhosis can act synergically towards HE development, and their prompt recognition influence patient's outcome.

CONCLUSIONS

HE is a frequent complication of liver cirrhosis, with increased prevalence in hospitalized cirrhotic patients. Infections, gastrointestinal bleeding, renal disfunction and dyselectrolytemia are the most common overall precipitating factors, and almost 40% of patients have multiple precipitating factors. According to cirrhosis etiology, a significant higher prevalence was found for sepsis and non-adherence in alcoholic cirrhosis, while HCC was significantly more frequent as precipitating factor in virus-related cirrhosis. Non-variceal bleeding was more frequent in alcohol-induced cirrhosis. Active exhaustive search and promptly control of the precipitating factors are mandatory and being aware of the risk factors could assure early identification and treatment.

NEWS

THE RELATIONSHIP BETWEEN EXERCISE CAPACITY AND NEUTROPHIL/LYMPHOCYTE RATIO

Neutrophil/lymphocyte ratio (NLR) has recently been used as a potential marker to determine inflammation in cardiac and non-cardiac diseases. Functional capacity, expressed as MET based on treadmill test, is one of the major prognostic factors in individuals with heart failure. The NLR value with a threshold level of 2.26 predicts a poor functional capacity with the sensitivity of 83% and specificity of 69%. Therefore, NLR was proposed as a useful tool to evaluate exercise performance of patients with heart failure. Similarly, NLR could also be used to predict functional capacity of patients before cardiac rehabilitation program. (Okan S. The relationship between exercise capacity and neutrophil//lymphocyte ratio in patients taken to cardiopulmonary rehabilitation program. *Bratisl Lek Listy* 2020; 121(3): 206-210)

INFECTIVE ENDOCARDITIS ETIOLOGIC PROFILE - STILL A CLASSIC DISTRIBUTION OF MICROORGANISMS?

INFECTIVE ENDOCARDITIS ETIOLOGIC PROFILE - STILL A CLASSIC DISTRIBUTION OF MICROOGANISMS? (Abstract): The present study analyzed etiologic profile of blood culture-positive infective endocarditis (IE) and possible differences between the main etiologies. **Material and methods:** An observational retrospective analysis was conducted in a regional hospital over 11-year period. A total of 58 consecutive patients diagnosed with infective endocarditis with positive blood cultures were included in the study. Diagnosis of IE was realized based on Duke modified criteria. All patients data was reviewed from electronic database and medical charts. Epidemiologic, clinical and laboratory parameters were analyzed. Afterwards, the main three determinant microorganisms were compared to identify differences in presentation or evolution. **Results:** Dominant etiology of IE was represented by: *Enterococcus spp.* (22.4%), *S. aureus* (18.9%), *Viridans streptococci* (17.2%), *S. gallolyticus* (10.3%) and coagulase-negative staphylococci (8.6%). Total in-hospital mortality remained high (24.1%), and no significative correlation was revealed between certain microorganism and worsening disease course (p=0.259), or in-hospital death (p=0.343). No major baseline characteristic or evolution differences were observed between the main 3 etiologies. *S. aureus* infection presented a significative association with thrombocytopenia (p=0.049) and high levels of total bilirubin (p=0.008). **Conclusions:** Infective endocarditis is still a community-acquired disease, with peculiar etiologic distribution and increased prevalence of *Enterococcus spp.* infection. In-hospital mortality of the disease remains high, independent of the etiologic profile. **Keywords:** INFECTIVE ENDOCADRITIS, ETIOLOGY, ENTEROCOCCUS SPP., EVOLUTION.

Infective endocarditis (IE) is a medical condition with high impact over mortality and morbidity due to frequent, late diagnosed, and impairing complications (1, 2). Even if the incidence of the disease is reported to be low, the diagnosis remains challenging in the context of heterogenous presentation. IE is one of the greatest "mimes" of pathology, from the well-known clinical picture of fever and new arise cardiac murmur, up to atypical presentations with the lack of fever, neuro-

logic, embolic, or systemic complications (1, 3).

Diagnostic and therapeutic options have improved over time, but the course of the disease remains unchanged. The high mortality, up to 30% of the cases, comparable with aortic dissection, makes infective endocarditis a fiercely opponent for the practitioner (4-5). It is often necessary for an "endocarditis team" to be formed, with the participation of different specialists, given the variable evolution and the need of a proper intervention to improve prognostic (1).

Nevertheless, blood cultures play a crucial role to the diagnostic of IE and to further treatment consideration. But some factors (as anterior treatment with antibiotics, or fastidious microorganisms) can lead to negative results of blood cultures (up to 50% of the cases), with subsequent difficulties in management and possible negative evolution of IE (6-7).

An epidemiological change appeared in the past 30 years, from a disease mainly affecting patients with rheumatic or congenital heart disease, determined by viridans streptococci, to one that is highly associated with degenerative heart diseases, medical interventions, often used cardiac devices or systemic procedures (dialysis, catheterization) and generated by species of staphylococci, or other aggressive microorganisms (3).

Over time, some etiologies of infective endocarditis show an increased prevalence, as it is reported for *Enterococcus spp*, a Gram-positive bacterium. The dominant species (up to 90%) is represented by *Enterococcus faecalis*. It was classical described as community acquired disease, low-symptomatic, with subacute evolution and of genito-urinary source, but nowadays it can also present as an acute, more aggressive healthcare associated infection, with antimicrobial resistance and challenges in diagnostic and treatment (8-10).

Our study aimed to assess the epidemiological profile of blood culture-positive IE in a regional hospital, to determine the distribution of microorganisms in the population and to identify differences related to etiology, data that could help in adapting therapeutic strategy, for reducing complications rate and improving disease's prognosis.

MATERIAL AND METHODS

We performed a descriptive analysis of the patients hospitalized with IE for 11-year period, from January 2007 to December 2017 in the Cardiology Department of "Sf. Spiridon" County Clinical Emergency Hospital Iasi, a regional center in North-East Romania. The study protocol was approved by the ethics committee and the hospital board. The investigation was in accordance with the Declaration of Helsinki.

From the 126 patients, 58 met the inclusion criteria for positive blood culture IE and were included in current analysis. Demographic, clinical, biological, imagistic characteristics of the patients, as well as the etiology of the infective endocarditis were recorded from electronic database or medical charts. A comparative analysis of the main 3 etiologies was performed.

Statistical analysis

Continuous variables are summarized by mean ± standard deviation (SD). Categoric variables are represented as percentages. Statistical significance was defined by a $p < 0.05$. Statistical analysis was performed using *SPSS version 24.0 software* (SPPS Inc., Chicago, IL, USA).

RESULTS

58 patients with blood culture-positive IE were included in the current analysis. Epidemiological characteristics, etiology, complications and evolution are presented in firs table.

TABLE I.

Characteristics of the study group

Parameters	**Patients, n=58**
Age, mean ± SD	58.29 ± 14.8
Gender ratio, n (%)	
Male	45 (77.5%)
Female	13 (22.4%)
Place of origin, n (%)	
Urban area	27 (46,5%)
Rural area	31 (53.4%)
Etiology of blood culture-positive IE, n (%)	
Enterococcus spp.	13 (22.4%)
Staphylococcus aureus	11 (18.9%)
Viridans streptococci	10 (17.2%)
Streptococcus gallolyticus	6 (10.3%)
Coagulase-negative staphylococci	5 (8.6%)
Neisseria sicca	2 (3.4%)
Klebsiella pneumoniae	2 (3.4%)
Pseudomonas spp.	2 (3.4%)
Group B streptococci	2 (3.4%)
Fungi	2 (3.4%)
Pasteurella pneumophilla	1 (1.7%)
Enterobacter spp.	1 (1.7%)
Streptococcus equi	1 (1.7%)
Cardiac involvement, n (%)	
Native valve	50 (86%)
Prosthetic valve	7 (12%)
Cardiac device lead	1 (1.7%)
Paravalvular complications, n (%)	9 (15.5%)
Embolic complications, n (%)	11 (18.9%)
Arrhythmias or conduction disorders, n (%)	
Atrial fibrillation	14 (24.1%)
AV blocks	4 (6.8%)
Associated diabetes mellitus, n (%)	10 (17.2%)
Cardiac predisposing condition, n (%)	27 (46.5%)
Days of hospitalization, mean ± SD	27,96 ± 15.98
In-hospital mortality, n (%)	14 (24.1%)

Abbreviations: AV= atrioventricular; IE = infective endocarditis; n = number; SD = standard deviation

No significative differences were observed between a certain microorganism and gender (p=0.116), history of predisposing cardiac condition (p=0.553), cardiac involvement (p=0.560), or paravalvular complications (p=0.947). Also, we did not

notice a significative distinction between etiologies and worsening disease (heart failure/ acute kidney failure/ hepatic dysfunction) (p=0.259), or in-hospital mortality (p=0.343).

The persistence of positive blood cultures after 10 days of antimicrobial treatment was associated with a higher in-hospital mortality (p=0.051). Other parameters for which we investigated a correlation with in-hospital mortality were cardiac involvement (p=0.484), paravalvular complications (p=0.132), patient gender (p=0.383).

Results of comparative analysis between the main 3 etiologies of IE are presented in second table II.

TABLE II.

Comparation between the main etiologies of IE

Parameter	*Enterococcus spp.* IE (n=13)	*S. aureus* IE (n=11)	Viridans streptococci IE (n=10)	p Value
Age, mean ± SD	63.38 ± 11.4	55.54 ± 18.32	63.8 ± 10.98	0.304
Male gender, n (%)	10 (76.9%)	7 (63.6%)	10 (100%)	0.116
Diabetes mellitus, n (%)	2 (15.3%)	1 (9%)	1 (10%)	0.874
Cardiac predisposing condition, n (%)	8 (61.5%)	5 (45.4%)	5 (50%)	0.553
Paravalvular complications, n(%)	2 (15.3%)	3 (27.2%)	1 (10%)	0.563
Embolic complications, n (%)	2 (18.1%)	4 (30.7%)	-	0.089

Abbreviations: AV= atrioventricular; Bilirubin (mg/dL); CRP = C-reactive protein (mg/dL); ESR = Erythrocyte Sedimentation Rate (mm/h); Fibrinogen (mg/dL); Hb = Hemoglobin (g/L); IE = infective endocarditis; n = number; Platelet (10^6/mm^3); RDW = Red Cell Distribution Width (%); SD = standard deviation; Serum creatinine (mg/dL); WBC = White Blood Cells (10^3/mm^3)

From all cases of *Enterococcus spp.* IE, 1 strain (7.6%) had intermediary sensibility to linezolid, the other cases didn't present resistance to vancomycin, linezolid, or imipenem. 2 cases (18.1%) of *S. aureus* IE presented intermediary sensibility to linezolid according with CLSI (Clinical Laboratory Standard Institute).

DISCUSSION

Infective endocarditis etiology is highly variable depending on the geographic area, development of the region, access to medical facilities and the emergence of different microorganisms. Blood cultures remain the key diagnostic tool in etiologic identification of IE, but a significant percent of cases have negative blood cultures (up to 30-50%) (1,11). Using advanced techniques of serological or molecular diagnosis can represent tools for microorganism identification, however their applicability is relatively low in the context of local lack of availability.

Mean age of diagnosis in this study was similar to other larger data presented - the 5th and 6th decades of life (8, 11-14), but different from a study conducted in Japan, which reported older mean ages for IE (69.1 years) and the difference can be explained by different life expectancy (7). Male gender was more affected by IE, in a comparable ratio of genders (3:1) as in the literature data (8, 11-14).

33.7% of the cases in EURO-ENDO had perivalvular extension of the disease (8). The large percent compared to current study (15.5%) can be determined by the involvement of more virulent bacteria, as *S. aureus*, which are known to have a more aggressive course, with potential of generating abscesses or prothesis dehiscence (15-16).

The rate of symptomatic embolic events (18.9%) was relatively similar to EURO-ENDO (25.3%), fact that underlines the high potential for vegetation embolization, with increased morbidity. Also, IE can induce conduction disorders or arrhythmic events, and this is evidence of local extension of the disease (8,17).

In our study, the etiologic distribution of microorganism is peculiar, with the predominance of enterococci (22,4%), *S. aureus* (18,9%), and viridans streptococci (17,2%). The results are different from large cohort trials, as the ESC-EORP EURO-ENDO registry, in which staphylococci were the main microorganism identified (44.1%), followed by oral streptococci (12.3%), enterococci (15.8%), and *S. gallolyticus* (6.6%) (8,9).

The relatively low prevalence of *S. aureus*, comparative to other studies, can be a consequence of the majority of community-acquired forms of IE in the current analysis. Also, we noticed a low number of prosthetic/device related cases (13.7%), in contrast with EURO-ENDO study (40%). The later named registry included a large number of healthcare associated IE (32.9%), opposite to current study, in which all the data collected was community-acquired IE. The underlined differences create the peculiar etiologic setting, being known that healthcare associated IE is more often determined by *Staphylococcus spp.*, or gram-negative bacteria, with higher virulence and multiple drug resistance (8).

In our study *K. pneumoniae* or *Pseudomonas spp.* were isolated in small percent (3.4%), but their potential for worse evolution because of their virulence in immunocompromised host in parallel with their level of resistance in our region, especially for healthcare associated infections it must force us to keep them under observation (18-19).

Also, an intriguing aspect is represented

by the emergence of *Enterococcus spp.* as a dominant etiology for IE. The EURO-ENDO registry also presented a high percent of cases as caused by *Enterococcus spp.* (16%) (8).

A study published by Ostgaard *et al* reported the highest prevalence for *Enterococcus spp.* IE (16.7%) in patients with blood stream infections, thus recommending screening for IE by echocardiography in all patients with *Enterococcus spp.* bacteriemia. The causative mechanism of disease and the increased prevalence of IE in the case of this specific microorganism is still debatable. What is certain, it represents a main determinant of IE with a reported frequency that increases with aging and highly associated with colorectal disease (20-22).

Our comparative analysis between the main three determinants of IE did not reveal major differences regarding baseline characteristics, evolution, or in-hospital death, but slightly distinctions in biologic profile were noted. *S. aureus* virulence and possibility to induce thrombocytopenia is known (23-26). Also, we observed a statistically significative increase of total bilirubin levels for *S. aureus,* compared to enterococci or viridans streptococci. This information may help in generating a profile of IE, and possibility to adapt empiric antimicrobial treatment, until the blood culture results (27).

Reported in-hospital death of 24.1% remains high compared to other registries (1,28), as EURO-ENDO, which presented an in-hospital mortality of 17.1% (8). This may be explained by differences in time setting of the current study compared to newer analysis, which have improved diagnosis and treatment options. Also, we note the decreased access to cardiac surgery, in contrast to west-European countries or other regional centers (8). In recent years, the number of these interventions has increased in our region, but let's not forget that the risk of healthcare associated infections is also increasing, especially in parallel with antibiotic resistance (29).

Our study has several limitations. It is a single center analysis, with a relatively decreased number of patients, but adjusted to the low incidence of IE. The wide distribution over time can generate variable statistical results and differences of disease's prevalence in the context of diagnostic techniques evolution. Nevertheless, the present study confers a local view of the etiology of IE and regional characterization, making possible a better understanding of the disease course.

CONCLUSIONS

Infective endocarditis is a challenging disease, in which community-acquired form still prevails, but has a peculiar distribution for etiology and high prevalence of *Enterococcus spp.* infection. In-hospital mortality of the disease remains high, independent of the etiologic profile.

RESIDUAL PERIODONTAL POCKET TREATMENT WITH ER: YAG LASER-ASSISTED COMPREHENSIVE PERIODONTAL POCKET THERAPY

A retrospective study realized by a Japanese group of researchers evaluated the safety and effectiveness of a novel pocket therapy using Er: YAG laser in combination with conventional mechanical scaling and root planning treatment. In the study were included forty sites in 29 elderly patients that have residual periodontal pockets of ≥ 5 mm depth, treated by curette and Er: YAG laser. After root debridement by curette, laser irradiation was performed on the root surfaces. The inflamed connective tissue on the inner gingival surface and on the bone surface/within extant bone defects was thoroughly debrided by curette and laser. In most cases, removal of the outer epithelium and coagulation of the blood clot in the pocket entrance were additionally performed with laser. The clinical parameters were evaluated before and 3, 6, and 12 months after treatment. The results showed that with Er: YAG laser-assisted pocket therapy, debridement of pockets was thoroughly, and safely performed, and favorable clinical improvements were observed in most cases. After 1-year, probing pocket depth significantly decreased from 6.4 ± 1.4 mm to 3.5 ± 1.3 mm ($p < 0.001$, 3.0 mm reduction), and clinical attachment level significantly decreased from 7.5 ± 1.6 mm to 5.2 ± 1.9 mm ($p < 0.001$, 2.3 mm gain). In conclusion, the obtained data indicate that Er: YAG laser-assisted therapy is useful for the treatment of residual pockets as a minimally invasive flapless surgery. (Aoki A, Mizutani K, Mikami R, *et al.* Residual periodontal pocket treatment with Er: YAG laser-assisted comprehensive periodontal pocket therapy: a retrospective study. *Clin Oral Investig* 2022; 26 (1): 761-771).

ETIOLOGIC SPECTRUM OF POST-OPERATIVE MENINGITIS IN NEUROSURGERY

ETIOLOGIC SPECTRUM OF POST-OPERATIVE MENINGITIS IN NEUROSURGERY (Abstract): Postoperative meningitis is a rare neurosurgical complication with an incidence of 0.3%-1.5%. The most common pathogen in postoperative meningitis in many studies was *Staphylococci*, especially *Staphylococcus aureus*, however recent data reports increasing rates of gram-negative organisms. **Material and methods**: We performed a retrospective study including 32 patients, diagnosed with post-craniotomy meningitis, who underwent neurosurgery, hospitalized between 2016 and 2019 in "Sf. Parascheva" Clinical Hospital of Infectious Diseases from Iasi, in order to evaluate the presence of pathogens in cerebrospinal fluid samples. **Results:** The most common pathogens were *Staphyloccoccus aureus, Streptococcus pneumoniae*, followed by *Acinetobacter speciae, Pseudomonas aeruginosa, Enteroccocus faecalis* and *Escherichia coli*. Antibiotherapy was properly administrated according to the antibiogram. **Conclusions:** Early diagnosis, appropriate antibiotic treatment and an interdisciplinary approach can lead to a favorable outcome. **Keywords:** POST-OPERATIVE MENINGITIS, ETIOLOGIC AGENT. NEUROSURGICAL COMPLICATION.

Postoperative meningitis is a rare neurosurgical complication, related to intraoperative incidental durotomy, with a high mortality and morbidity rate, associated with severe neurological symptoms, prolonged hospitalization and expensive treatment (1). The incidence of meningitis after neurosurgery ranges between 0.3% and 1.5% but increases up to 22% if the patient requires shunts or devices to drain cerebrospinal fluid (CSF) or to monitor intracranial pressure (external ventricular drains or external spinal drains) (2). There is fewer data regarding the clinical course of postoperative meningitis, however the presence of consciousness disturbance, neck stiffness and fever after neurosurgery can raise suspicions of postoperative meningitis. Any delay in establishing the correct diagnosis and starting proper treatment can lead to high morbidity and mortality (3). The most common pathogen in postoperative meningitis in many studies was *Staphylococci*, especially *Staphylococcus*

aureus, however recent data reports increasing rates of gram-negative organisms (*Acinetobacter baumannii, Pseudomonas aeruginosa, Klebsiella pneumoniae*), *Streptococcus pneumoniae, Enterococcus faecalis* and also fungal agents, such as *Candida speciae* (most frequent *Candida albicans*). Bacteria and fungi can be cultured from CSF, but in 54-70% of cases there is no bacterial/fungal growth on CSF cultures (called 'aseptic meningitis') (4). Empiric therapy for post-neurosurgical meningitis should be elected taking into consideration the most likely pathogens involved and should be based on the local resistance pattern (5).

MATERIAL AND METHODS

We performed a retrospective study, including 32 patients, diagnosed with post-craniotomy meningitis, from a total of 627 patients, who underwent neurosurgery, hospitalized between 2016 and 2019 in the "Sf. Parascheva" Clinical Hospital of Infectious Diseases, Iasi, in order to evaluate the presence of pathogens in CSF samples.

RESULTS

Our study reported 5,1% incidence of post-craniotomy meningitis. The study group consisted of 20 males (62.5%) and 12 females (37.5%), mostly aged under 60 (75%), living in rural areas (68.75%) (fig. 1). Almost 20% of patients declared a history of meningitis in their medical records.

Over 50% of patients presented underlying medical conditions, such as: cardiovascular diseases (most frequent: arterial hypertension - 50%, myocardial infarction - 31.125%), neoplasia (12.5%), diabetes mellitus (9.375%), pulmonary pathology (9.375%), liver dysfunction (9.375%), renal impairment (6.25%), and obesity (3.125%) (fig. 2).

In 50% of cases, CSF cultures identified a pathogen responsible of post-craniotomy meningitis. The most common pathogen was *Staphyloccoccus aureus* - 5 cases (25%), followed by *Streptococcus pneumoniae* - 4 cases (20%), *Acinetobacter speciae* - 4 cases (20%), *Pseudomonas aeruginosa* - 3 cases (15%) and *Escherichia coli* - 2 cases (10%), *Enterococcus faecalis* - 2 cases (10%) (fig. 3).

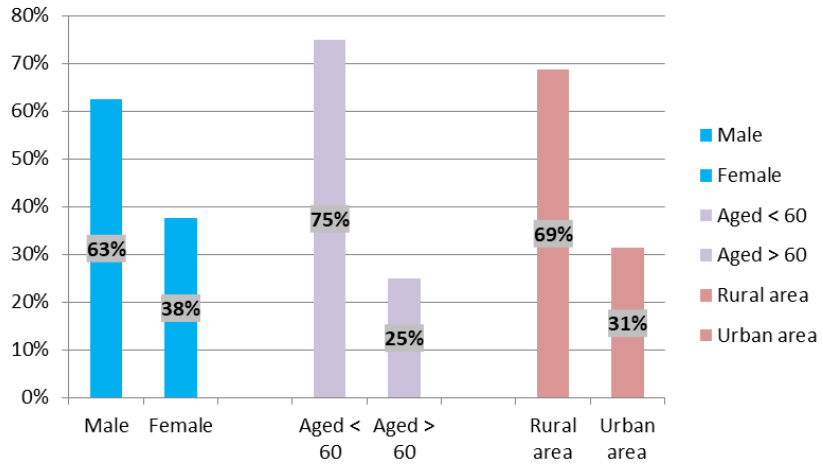

Fig. 1. Characteristics of the patients included in the study

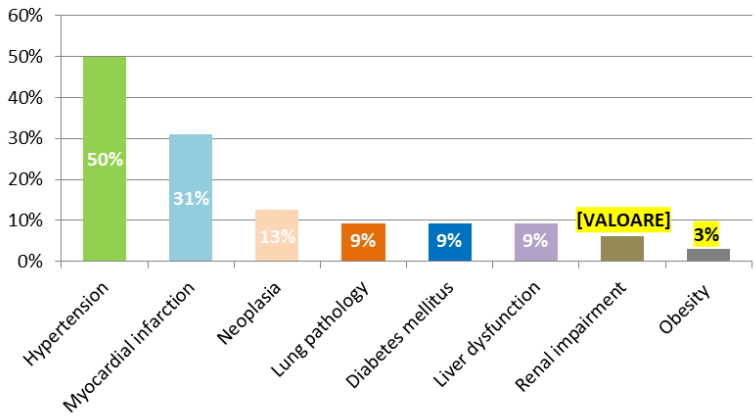

Fig. 2. Associated medical conditions in patients with post-craniotomy meningitis

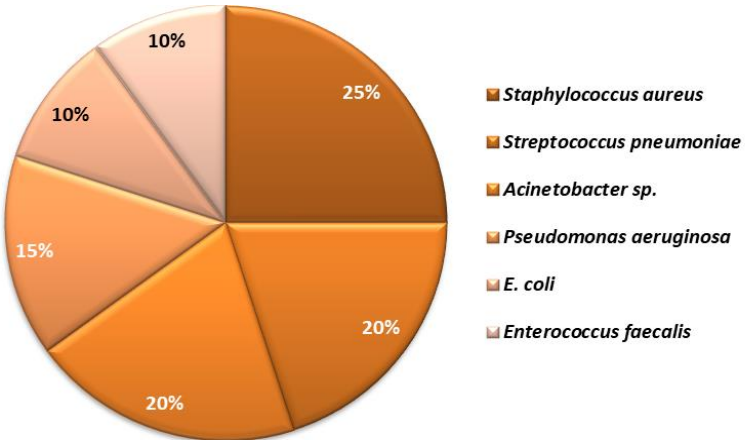

Fig. 3. Most common pathogens identified in CSF cultures

Antimicrobial susceptibility of isolates was determined using the disk diffusion method and every antibiotherapy was administered according to antibiogram. Most commonly, *Staphylococcus aureus* strains were methicillin resistant, with antimicrobial susceptible to glycopeptides (Vancomycin). All *Streptococcus pneumoniae* strains were sensitive to vancomycin, linezolid, levofloxacin, rifampicin and chloramphenicol (not used due to hematologic side effects) and resistant to penicillin. The high rate of *Acinetobacter baumannii* carbapenem-resistant has led to polymyxin B administration (intrathecal use of colistin). The treatment of *Pseudomonas aeruginosa* initially included cephalosporins (Ceftazidime), but afterwards it was switched to carbapenems (Meropenem). A switch from cephalosporins (Cefotaxime, Ceftriaxone) to carbapenems (Meropenem) was also performed in *Escherichia coli* strains. *Enterococcus faecalis* isolates were mostly treated with beta-lactam antibiotics and carbapenems, due to high incidence of vancomycin-resistance (tab. I).

TABLE I.
Etiologic agents in post-operative meningitis

Identified etiologic agent	Antimicrobial susceptibility	Number of cases	Percentage
Staphylococcus aureus	Glycopeptides (Vancomycin)	5	25%
Streptococcus pneumoniae	Glycopeptides (Vancomycin), Fluoroquinolones, Linezolid, Rifampicin	4	20%
Acinetobacter baumannii	Carbapenems (Meropenem) or Polymyxin (Colistin)	4	20%
Pseudomonas aeruginosa	Cephalosporins (Ceftazidime), Carbapenems (Meropenem)	3	15%
Escherichia coli	Cephalosporins (Cefotaxime, Ceftriaxone), Carbapenems (Meropenem)	2	10%
Enterococcus faecalis	Beta-lactam antibiotics, Carbapenems (Meropenem)	2	10%

The median period of treatment was 18 days, with favorable course in 23 cases (71.87%) and fatal evolution in 4 cases (12.5%).

DISCUSSION

Our study aimed to evaluate the presence of pathogens in CSF samples submitted to conventional culture, from patients who underwent craniotomy and had presented acute clinical manifestations compatible with meningitis, confirmed by neurologists, neurosurgeons or infectious diseases specialists. Diagnosis of meningitis was defined as a positive CSF culture, associated with meningitis signs and/or symptoms (fever, headache, neck stiffness, photophobia, neurologic symptoms) (6, 7).

It is unlikely that our results were obtained through contamination of the samples, since other postoperative patients without symptoms of meningitis were tested under the same conditions and none produced a positive CSF culture. Therefore, the etiologic agent was not identified in all 32 cases, due to the fact that patients were administered pre-operative antibiotherapy.

Blood and CSF samples were periodically tested in order to evaluate improvement or normalization of the biological parameters.

Also, daily clinical evaluations were performed on every patient by an interdisciplinary team (neurologist/neurosurgeon, infectious diseases and intensive care specialists).

CONCLUSIONS

This study confirmed that postoperative meningitis is a rare post-neurosurgical complication. A lumbar puncture should be performed for every patient with suspected meningitis, after undergoing neurosurgery, if there are no contraindications.

Early diagnosis, appropriate antibiotic/antifungal treatment and an interdisciplinary approach can lead to a favorable outcome.

NEW INTRANASAL AND INJECTABLE GENE THERAPY FOR HEALTHY LIFE EXTENSION

As the global elderly population grows, it is socioeconomically and medically critical to provide diverse and effective means of mitigating the impact of aging on human health. Previous studies showed that the adeno-associated virus (AAV) vector induced overexpression of certain proteins, which can suppress or reverse the effects of aging in animal models. In our study, we sought to determine whether the high-capacity cytomegalovirus vector (CMV) can be an effective and safe gene delivery method for two such protective factors: telomerase reverse transcriptase (TERT) and follistatin (FST). We found that the mouse cytomegalovirus (MCMV) carrying exogenous TERT or FST (MCMVTERT or MCMVFST) extended median lifespan by 41.4% and 32.5%, respectively. We report CMV being used successfully as both an intranasal and injectable gene therapy system to extend longevity. Specifically, this treatment significantly improved glucose tolerance, physical performance, as well as preventing body mass loss and alopecia. Further, telomere shortening associated with aging was ameliorated by TERT and mitochondrial structure deterioration was halted in both treatments. Intranasal and injectable preparations performed equally well in safely and efficiently delivering gene therapy to multiple organs, with long-lasting benefits and without carcinogenicity or unwanted side effects. Translating this research to humans could have significant benefits associated with quality of life and an increased health span (Jaijyan DK , Selariu A , Cruz-Cosme R , *et al.* New intranasal and injectable gene therapy for healthy life extension. *Proc Natl Acad Sci USA* 2022: 119(20): e2121499119).

CONSIDERATIONS ON CASES OF DIFFUSE AXONAL INJURY AUTOPSIED IN THE INSTITUTE OF FORENSIC MEDICINE IASI, ROMANIA

CONSIDERATIONS ON CASES OF DIFFUSE AXONAL INJURY AUTOPSIED IN THE INSTITUTE OF LEGAL MEDICINE IAȘI ROMANIA (Abstract) : Traumatic brain injury (TBI), mainly caused by road traffic accidents and falls, is one of the main causes of mortality. Survivors often present with debilitating motor, sensory and cognitive symptoms, leading to a reduced quality of life and a profound economic burden on society. **Material and methods**: The study was conducted by analyzing forensic cases autopsied at the Institute of Forensic Medicine Iasi, between 2015-2020, diagnosed antemortem with traumatic brain injury and *diffuse axonal injury* (DAI). The analysis includes a retrospective study of the forensic necropsy cases conducted between 2015-2020. Data were loaded and processed using statistical functions in *SPSS 18.0* at the 95% significance level. **Results:** The analysis of forensic cases autopsied at the Institute of Forensic Medicine Iasi between 2015-2020 showed a number of 7818 autopsied cases, of which 3545 were violent deaths. Of these, 567 had as cause of death craniocerebral trauma; of these only 70 cases were accompanied by the imaging diagnosis of DAI, which corresponds to 12% of all cases of craniocerebral trauma. **Conclusions**: The imaging diagnosis of DAI was refuted by pathological examination in 24 of the cases, out of a total of 70 patients with a radiological diagnosis of DAI, corresponding to 34.28% of cases. The survival rate of rural patients was significantly higher (14.27 *vs.* 7.33 days; p=0.03). Patients with DAI have a high mortality, supported by a 50% decrease after the first week in the chance of survival. **Keywords**: DIFFUSE AXONAL INJURY, TRAUMATIC BRAIN INJURY, AUTHOPSY, RESTROSPECTIVE STUDY.

Diffuse axonal injury (DAI) was first reported in the literature by Sabina J. Strich in 1956 (1). In her paper, Strich described five victims with severe dementia following traumatic brain injury who, at autopsy 5-15 months after injury, showed diffuse

degeneration of cerebral white matter. Adams and Genarelli's work explains the biomechanics of these injuries by incriminating acceleration-deceleration forces and angular acceleration (2-5). Primate studies have explained comatose states in patients with traumatic brain injury (TBI) without focal brain lesions by the detection of DAI. Specifically, axonal lesions have frequently been found at sites of predilection primarily involving the subcortical white matter of the frontal and temporal lobes, the corpus and splenium of the corpus callosum and, in the most severe cases, the rostral superior region of the brainstem (6,7). Currently, DAI is considered a common finding in patients suffering from TBI, existing in approximately half of closed TBI cases in combination with focal lesions. Isolated DAI are less common (8). However, DAI have a particularly negative impact on outcomes, as patients are frequently left with severe motor, cognitive and behavioral impairments (9). Our study aims to highlight the main necropathic features of TBI, by analyzing forensic cases autopsied at the Institute of Forensic Medicine Iasi Romania in the period 2015-2020, diagnosed antemortem, by CT examination, with DAI.

MATERIAL AND METHODS

The study was conducted by analyzing forensic cases autopsied at the Institute of Forensic Medicine Iasi. diagnosed antemortem with traumatic brain injury and DAI. The analysis includes a retrospective study of the forensic necropsy cases conducted between 2015-2020.

A study group was selected that included all cases of death due to traumatic brain injury with associated DAI. Only cases in which TBI was stated on the death certificate as the cause of death regardless of the presence of lesional associations were included in the study.

Data were loaded and processed using statistical functions in *SPSS 18.0* at the 95% significance level. Tests such as ANOVA, Skewness or Kurtosis tests ($-2 < p < 2$), Friedman test, Kruskal-Wallis test, t-Student test, F-test and multivariate analysis were used for the data presented in this study; the threshold of statistical significance was set a priori at 0.05. Data are expressed numerically or as a percentage of the whole.

Inclusion criteria: cranio-cerebral trauma with associated DAI, autopsied at the Institute of Legal Medicine Iasi Romania, between 2015-2020;

Exclusion criteria: cardiovascular disease and history of stroke, cases suffering from loss of vital functions, post-traumatic survival time of less than 20 minutes, chronic alcoholism, absence of hospitalizations after trauma, absence of associated DAI on CT examination, GSC >8, autolysis and putrefaction; this study was conducted in accordance with the standards developed by the Declaration of Helsinki, the approval of the management of the Institute of Forensic Medicine Iași, Romania (No.12/2020). Informed Consent for the autopsy is not required, the autopsy is mandatory under Romanian Law (Romanian Criminal Procedure Code Law No. 135/2010, chapter VII, article 185).

RESULTS

The analysis of forensic cases autopsied at the Institute of Forensic Medicine Iasi between 2015-2020 showed a number of 7,818 autopsied cases, of which 3,545 were violent deaths. Of these, 567 had as cause of death craniocerebral trauma; of these

only 70 cases were accompanied by the imaging diagnosis of DAI, which corresponds to 12% of all cases of cranio-cerebral trauma (figs. 1, 2).

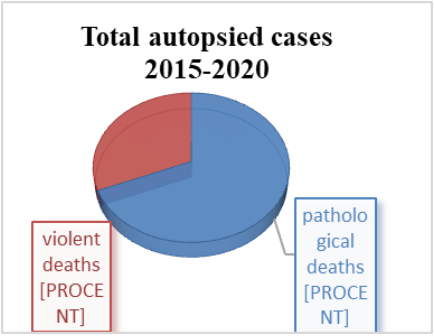

Fig. 1. Violent deaths out of all autopsied cases

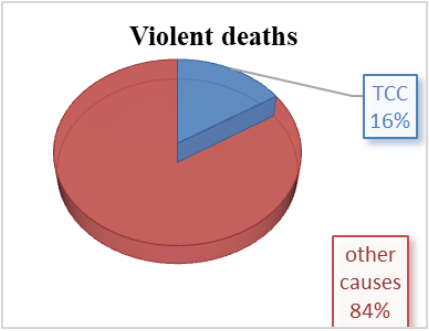

Fig. 2. Causes of death by TBI out of all violent deaths

Demographic characteristics

Gender distribution

The distribution of cases by sex showed a higher proportion of male cases (74.3%), with a M/F ratio of 2.9 : 1 (fig. 3).

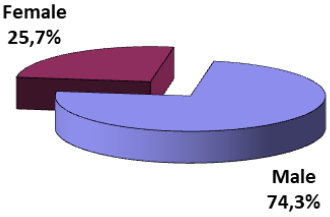

Fig. 3. Batch structure by gender

Distribution by age group

The age of patients with traumatic brain injury accompanied by DAI shows the following characteristics (tab. I, fig. 4).

The histogram of ages shows the following data: variations in the range 22-86 years; group mean 51.34 ± 15.38 years; median = 50 years; Skewness test result p = 0.224; the median value close to the mean age of the group and the Skewness test result < 2 suggest that the age range was homogeneous, so significance tests for continuous variables can be applied.

	75	62

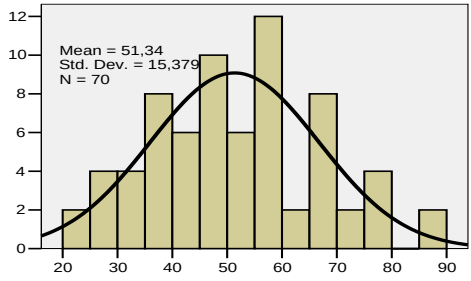

Fig. 4. Histogram of ages

The highest frequency of patients are aged over 50 years (51.4%), with no significant gender differences (53.8% of men *vs.* 66.7% of women; p=0.130) (fig. 5).

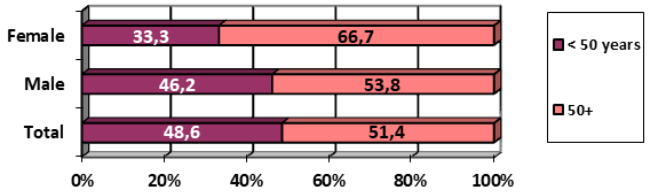

Fig. 5. Batch structure by age group and gender

Distribution by background

In the present study group, the proportion of rural patients was higher (65.7% *vs.* 34.3%), with no significant gender differences (65.4% of men *vs.* 66.7% of women; p=0.921) (fig. 6).

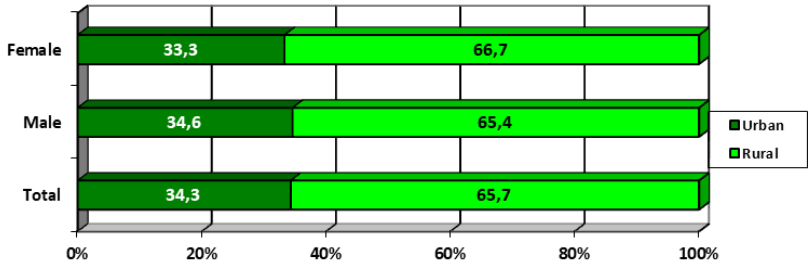

Fig. 6. Batch structure by background and gender

Clinical parameters

Mechanism of trauma production

37.1% of the patients had falls from the same level as the reason for the injury and 31.4% had road traffic accidents (fig. 7).

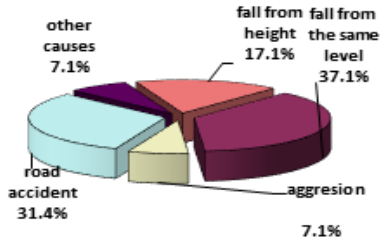

Fig. 7. Distribution of patients by mechanism of production of trauma

Depending on the presence of DAI confirmed by histopathological examination, the study group was divided into two subgroups: DAI group = 46 patients with histopathologicaly confirmed diffuse axonal lesions and non-DAI group = 24 patients with histopathologicaly confirmed diffuse axonal lesions.

The frequency of patients with confirmed diffuse axonal lesions was higher in males (73.9% *vs.* 26.1%; p=0.921), in those under 60 years of age (52.2% *vs.* 47.8%; p=0.408) and in those from rural areas (65.2% *vs.* 34.8%; p=0.903) (tab. II, fig. 8). Of the patients with DAI, 41.3% had suffered a fall from the same level and 32.6% had acquired the lesion following a road traffic accident, whereas in patients without histopathologicaly confirmed traumatic axonal lesions, 33.3% had fallen from a height (p=0.037) (tab. III, fig. 9). This contradicts data in the literature identifying road traffic accidents as the main traumatic context for the development of DAI.

TABLE II.

Group structure according to the presence of DAI

Features	Batch TAI (n=46)		Non-TAI batch (n=24)		p
	n	%	n	%	
Male	34	73.9	18	75.0	0.921
Female	12	26.1	6	25.0

Rural	30	65.2	16	66.7	

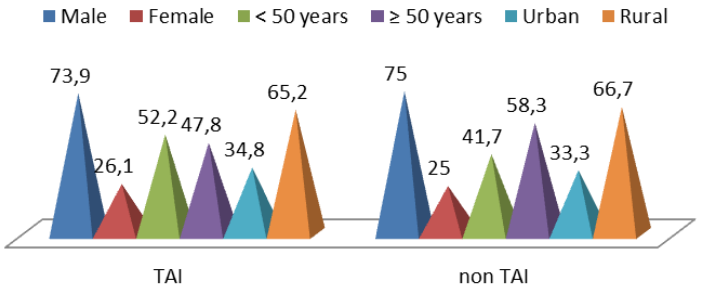

Fig. 8. Epidemiological characteristics according to the presence of DAI

TABLE III.

Correlation of DAI with the mechanism of production

Production mechanism	Batch TAI (n=46)		Non-TAI batch (n=24)	
	n	%	n	%
Fall from height	4	8.7	8	33.3
Fall from the same level	19	41.3	7	29.2
Aggresion	3	6.5	2	8.3
Road accident	15	32.6	7	29.2
Another cause	5	10.9	0	0

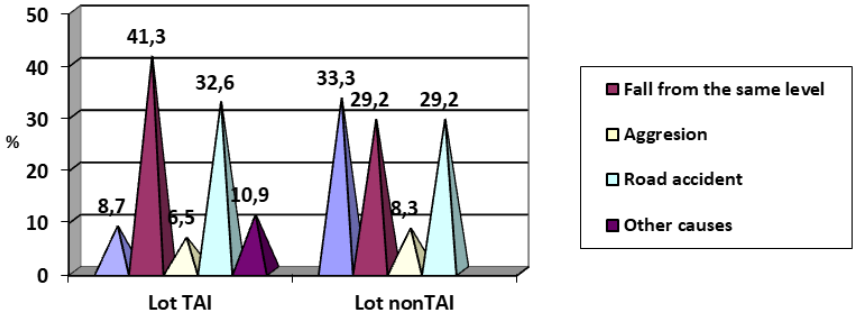

Fig. 9. Production mechanism depending on the presence of DAI

The CT result showed in those with histopathologicaly confirmed DAI, most commonly 28.6% fractures and 25.7% contusions or hematomas (fig. 10).

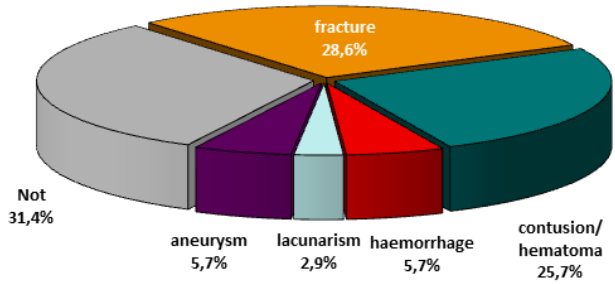

Fig. 10. Batch structure according to CT result

Survival days

The descriptive data on the number of survival days highlights the following aspects (tab. IV, fig.11):

TABLE IV.

Estimated risk of DAI based on CT result

Features	Batch TAI (n=46)	Non-TAI batch (n=24)	p	Estimated risk	
				RR	CI 95%
Fracture	12 (26.1%)	8 (33.3%)	0.527	0.88	0.59-1.32
Intracerebral contusion/ hematoma	18 (39.1%)	0 (0%)	**0.001**	1.86	1.44-2.39
Other	4 (8.6%)	2 (8.3%)	0.959	1.02	0.56-1.84

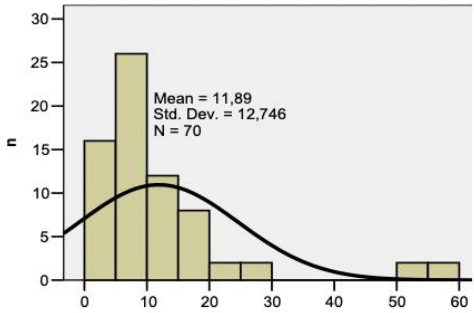

Fig. 11. Histogram of survival days

The histogram of survival day shows the following data: wide variations (72.42%) from a few hours to 60 days; group average 11.89 days ± 12.75 ; median = 8 days; Skewness test result p = 1.602; the median value at relatively close to the mean number of survival days of the group and the result of the Skewness test < 2

suggests that the series of survival days values was homogeneous, so significance tests for continuous variables can be applied; the mean number of days in hospital was slightly lower in males (11.04 *vs.* 14.33 days; p=0.349) and in those aged over 50 years (11.62 *vs.* 12.18 days; p=0.856) (figs. 12, 13 and tab. V).

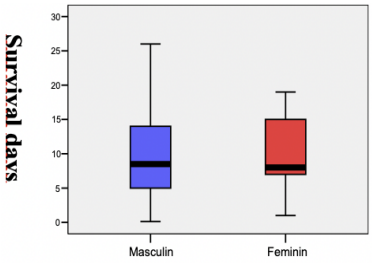

Fig. 12. Average number of survival days comparison by gender

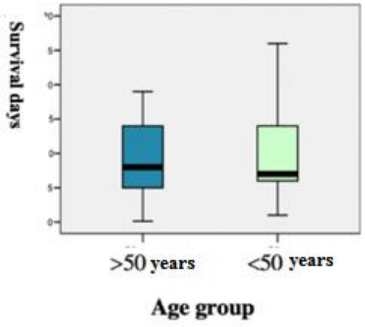

Fig. 13. Average number of survival days comparison by age group

TABLE V.

Statistical indicators for the number of survival days

N		70
Medium		11.89
Median		8
Standard Deviation		12.75
Variance		72.42
Skewness Test		1.602
Std. Error of Skewness		0.287
Minim		0
Maxim		60
Percentile	25	5
	50	8
	75	14

Of note, the mean number of survival days was significantly higher in patients from rural areas (14.27 *vs.* 7.33 days; p=0.03) (tab. VI).

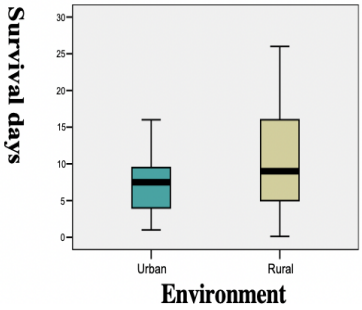

Fig. 14. Mean number of survival days compared by environment

TABLE VI.

Average number of survival days according to epidemiological characteristics

Features	Days survival ±SD	t-Student test (p)
Male	11.04 ± 10.76	0.349
Female	14.33 ± 17.42	
Age < 50 years	12.18 ± 11.73	0.856
Age ≥ 50 years	11.62 ± 11.73	
Rural	14.27 ± 14.88	**0.030**
Urban	7.33 ± 4.59	

In patients with histopathologicaly confirmed DAI, the probability of survival falls below 50% after 7 days (fig. 15), which correlates DAI with high mortality.

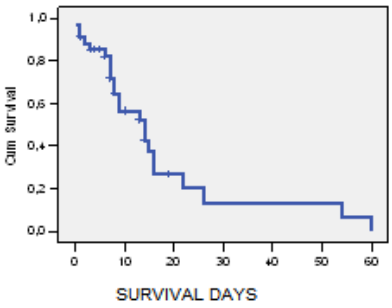

Fig. 15. Probability of survival in patients with DAI

DISCUSSION

The analysis of forensic cases autopsied at the Institute of Forensic Medicine Iasi between 2015-2020 showed a number of 7818 autopsied cases, of which 3545 were violent deaths. Of these, 567 had as cause of death craniocerebral trauma; of these only 70 were accompanied by the imaging diagnosis of DAI, which corresponds to 12% of all cases of craniocerebral trauma. An increased prevalence of traumatic brain injury was observed in males (74.3%) and in the over 50 age group (51.4%). The data obtained is consistent with the statistics in the literature in terms of gender, but inconsistent in terms of the age category most commonly affected, which states that young adults are most commonly involved. The frequency of patients with histological confirmed diffuse axonal lesions was higher in males (73.9% *vs.* 26.1%; p=0.921), those under 60 years of age (52.2% *vs.* 47.8%; p=0.408) and those from rural areas (65.2% *vs.* 34.8%; p=0.903). Skull fractures were observed in 59.4% of the cases of traumatic brain injury with associated imaging-diagnosed DAI, of which the highest incidence was identified in patients without histopathologicaly confirmed DAI (33%). In the histopathologicaly confirmed DAI group, the incidence of skull fractures was 26.1%, which confirms literature data that DAI is more common in patients with closed head injury. The most common DAI-associated injuries were concussions and intracerebral haematomas.

The mechanism of occurrence most frequently associated with DAI was falling from the same level (41.3%), which contradicts the literature, which argues that road traffic accidents are the most common mechanism involved in causing DAI. On the other hand, those involved in road traffic accidents may have had a survival time of less than 20 minutes due to associated serious injuries, with survival time of less than 20 minutes being one of the exclusion criteria in this case. In patients with histopathologicaly confirmed DAI, the probability of survival falls below 50% after 7 days. The mean number of days of survival was significantly higher in patients from rural areas (14.27 *vs.* 7.33 days; p=0.03).

CONCLUSIONS

DAI is a leading cause of mortality and permanent morbidity worldwide. The imaging diagnosis of DAI was refuted by pathological examination in 24 of the cases, out of a total of 70 patients with a radiological diagnosis of DAI, corresponding to 34.28% of cases. The certainty diagnosis for the presence of DAI remains the anatomopathological one.

The survival rate of rural patients was significantly higher (14.27 *vs.* 7.33 days;

p=0.03). Patients with DAI have a high mortality, supported by a 50% decrease after the first week in the chance of survival. The most frequently detected imaging brain lesions associated with DAI were contusions.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

AN UNANTICIPATED OBSERVATION REGARDING FGF23 DURING ONE YEAR OF GH REPLACEMENT THERAPY

AN UNANTICIPATED OBSERVATION REGARDING FGF23 DURING ONE YEAR OF GH REPLACEMENT THERAPY (Abstract): To promote linear growth, it is essential to have normal phosphate homeostasis. Growth hormone/insulin-like growth factor (GH/IGF1) axis is a major regulator of phosphate metabolism and children with growth hormone deficiency (GHD) have increased renal phosphorus reabsorption during rhGH therapy. The novel phosphaturic fibroblast growth factor 23 (FGF23) has opposing effects, but the underlying mechanisms and interplay between both systems remain unclear. **Aim:** The main objective of this study is to investigate the possible interactions of FGF23 with the GH/IGF1 axis in the regulation of growth, calcium-phosphorus metabolism, and bone mineral density (BMD) in GHD children during the first year of treatment. **Material and methods:** Prospective, observational study of 42 non-obese prepubertal GHD children of both sexes, investigating changes in plasma FGF23, markers of mineral metabolism, and IGF-1 in the first year of rhGH therapy. **Results:** All children grew at an accelerated pace. Total BMD and total bone mineral content significantly increased after 12 months. The increase in serum phosphate was accompanied by a significant increase in plasma cFGF23 and IGF1. We found a positive association between SDS Height with IGF1 and FGF23 levels. No impact of FGF23 concentration variations on BMD was determined. **Conclusions:** FGF23 rises during rhGH therapy, an unanticipated observation given the role of FGF23 as a phosphaturic factor. GHD children have increased phosphate, associated with upregulation rather than with suppression of the phosphaturic FGF23. The association of FGF23 with height and IGF1 could indicate complex interactions between both axes in promoting linear growth. **Keywords**: GH DEFICIENCY, FGF23, BMD, IGF1.

Linear growth is influenced by numerous nutritional, metabolic, and hormonal factors, of which growth hormone (GH), calcium-phosphorus homeostasis, and bone-kidney endocrine axis mediated by the novel phosphaturic hormone fibroblast growth factor 23 (FGF23), play a critical role in appropriate bone and growth plate mineralization (1, 2, 3).

It is well acknowledged that children with GH deficiency (GHD) have smaller stature and reduced longitudinal bone growth (3, 4), with a lower bone mineral density (BMD) and delay in skeletal maturation, thus emphasizing the key role of GH/IGF1 axis in adult BMD outcomes and

the need for continuing replacement treatment during the transition from pediatric to adult age (5). The rhGH treatment determines the normalization of BMD, the most important predictor of osteoporotic fractures, with modifications in markers of bone formation and bone resorption right from the beginning of therapy (4, 5, 6).

The attainment of optimal BMD and bone growth is also influenced by the calcium-phosphorus metabolism and the more recently uncovered bone-kidney endocrine axis. In addition to the well-known paradigm of the vitamin D-parathyroid hormone endocrine system, other factors control the maintenance of phosphate homeostasis: dietary intake, intestinal absorption, chronological age (7). In addition to these dynamics, FGF23, predominantly produced by osteocytes, is a key element in regulating phosphorus metabolism with skeletal mineralization. It has been demonstrated that GHD children have increased renal phosphorus reabsorption during replacement therapy, which are accompanied by non-suppressed FGF23 levels (2, 8).

At the same time, the somatotropic axis influences calcium-phosphorus metabolism through a mechanism opposite to FGF23, causing renal phosphate reabsorption (9). Thus, GHD patients have a relative phosphorus deficiency status, and GH therapy increases renal phosphate reabsorption, but the underlying pathways remain uncertain (10). Thereby, we might be tempted to believe that a possible mechanism of GH/IGF1-induced hyperphosphatemia is through inhibition of FGF23, but current studies do not support this theory, as FGF23 levels are elevated in patients with active acromegaly (11) and GH treatment increased the levels of FGF23 in children with GHD (2, 8). Thus, the increase in serum phosphate by GH therapy seems to not be mediated through the suppression of the phosphaturic FGF23 (2). Studies reported a strong positive association of FGF23/Klotho axis with IGF-I and height that could indicate a role in linear growth through phosphate regulation (1).

There is scarce data available regarding the consequences of childhood-onset GHD on BMD. However, it has been reported that GH therapy should minimize, if not prevent the higher fracture risk associated with the lack of GH (3, 5). Moreover, although our understanding of phosphate homeostasis has been dramatically increased from previous studies, the interplay between FGF23, GH/IGF1 axis, and BMD is not fully elucidated and data in GHD children are limited. Some studies suggest that there may be a causal relationship between FGF23 levels and BMD and that a high concentration of FGF23 is associated with a low BMD in adults (12, 13, 14).

The main objective of our study is to investigate the possible interactions of FGF23 with the GH/IGF1 axis in the regulation of calcium-phosphate metabolism and BMD in GHD children during one year of GH replacement therapy.

MATERIAL AND METHODS

This was a prospective, observational study with consecutive sampling of non-obese prepubertal GHD children of both sexes. The study was carried out at the Endocrinology Clinic, "Sf. Spiridon" Emergency Hospital in Iași, Romania, following approval by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy from Iași and the written informed consent of the patients and their parents prior to participation.

A total of 42 children (14 girls, 28

boys) diagnosed with idiopathic GHD were included and started on a twelve-month course of GH therapy. The starting mean age of the children was 9.2 ± 2.6, with no significant differences between sexes. All subjects were prepubertal (Tanner Stage I) and maintained this status during the observation period. The diagnosis of GHD was established in accordance with the national GH treatment protocol and criteria (15), namely a maximum GH peak of 7 ng/mL in two GH provocation tests. Other possible etiologies for short stature were excluded (15). Magnetic resonance imaging was performed, and it showed normal hypophysis in all subjects. The exclusion criteria were pubertal onset, overweight or obese status, and concomitant existence of other metabolic disorders or diseases.

Longitudinal study. GHD children started GH replacement therapy at 0.030 mg/kg per day and upheld it for twelve months. Changes in body composition, calcium-phosphorus metabolism, and levels of serum C-terminal FGF23 were monitored thrice, first before initiating GH therapy, then at six and twelve months.

Blood sampling and biochemical analysis. At the first visit, a detailed clinical history was obtained and age, sex, weight (kg), height (cm), BMI (weight/height^2), and bone age were recorded. Morning blood samples were collected after 12 hours of fasting and then were immediately frozen at -45°C until analysis. Serum fasting IGF-I, IGF1-BP3, C-terminal FGF23, phosphorus, total calcium, magnesium, creatinine, alkaline phosphatase (ALP), 25-OH-vitamin D, parathormone and anthropometric parameters were evaluated in all patients at baseline, after 6 and 12 months of rhGH replacement therapy.

Serum C-terminal FGF23 was measured by enzyme-linked immunosorbent assay (ELISA, SEA746Hu, USCN Life Sciences, Wuhan, China; intra-assay variability of 6.96%), which measures both the active and the inactive FGF23 obtained after proteolytic cleavage of FGF23 in EDTA plasma centrifuged straight away after collection. Body composition was evaluated by total body dual-energy x-ray absorptiometry using a Hologic QDR-4500 densitometer.

Statistical analysis. Using *SPSS 24.0*, we performed a comparative study of the monitored parameters. The results are expressed as mean ± SEM (standard error of the mean) unless otherwise stated. After testing the normal distribution of data, we compared the three sets of values with the Student's t-test for paired samples and the Wilcoxon test when normal distribution was not observed. The correlations between changes in variables were evaluated using regression analysis. If statistically significant associations were identified, the regression line was constructed to estimate the intensity of these correlations. We used the standard multiple regression method to investigate the connection between several variables. To establish if the built model fits the data, we analyzed the coefficient of determination, and we considered $p<0.05$ as the threshold for statistical significance in the ANOVA test.

RESULTS

The baseline, 6- and 12-month analytic data are presented in figures 1 and 2.

All children grew at an accelerated pace, with a mean growth of ~8 cm/12 months (ΔSD height=0.57±0.24, ΔSD height velocity=1.39 ±1.53). Weight and BMI also increased steadily and significantly during the monitoring year by ~4 kg

and 0.6 units respectively (shown in Fig. 1, upper panel, ΔSD_BMI=1.88±0.43). The total body fat (BF) content and %BF registered a significant decrease throughout the study period. Instead, the lean mass increased steadily, with statistically significant differences among all three evaluations (fig. 1, lower panel). Total BMD and BMC significantly increased after 12 months, while total calcium did not show significant variations (fig. 2). The increase in serum phosphate was accompanied by a significant increase in plasma cFGF23 and IGF1 (fig. 1 middle panel and fig. 2 lower panel).

The dynamic relationship between FGF23, body composition and GH therapy

The **correlations** between body composition, calcium-phosphorus metabolism, and FGF23 levels at the three-time points are shown in tables I and II.

Results are expressed as coefficient r and p, with bold-significant correlations;
PTH, Parathyroid hormone; PO4, serum phosphorus; ALP, alkaline phosphatase.

GH therapy resulted in a significant improvement in the lumbar Z-score, with a significant increase in total, lumbar and neck BMD, and BMC. FGF23 values are also relatively sporadically correlated with body composition parameters. IGFBP3 is statistically significantly correlated, at all 3-time points of the assessment, with most parameters of body composition (tab. I). Serum phosphate was positively related to FGF23 (r=0.550; P<0.0001) and IGF1 (r=0.385; P<0.05). FGF23 values are proportional and positively correlated with Height (tab. I). At the 6-month evaluation, we detected moderate positive correlations of FGF23 with alkaline phosphatase, IGF1, and DS IGF1, while at the 12-month evaluation, FGF23 moderately correlated with alkaline phosphatase (tabs. I and II).

Further on, we performed dynamic correlations between variations (Δ=T12 - T0) of variables to assess the effect of GH replacement therapy compared to the effect of body composition changes upon the modifications in FGF23, after 12 months of therapy. Significant correlations were afterward introduced in regression models adjusted for age, sex, serum phosphate levels, 25 (OH) vitamin D, IGF-I, and PTH. We have included all the above parameters in the model, and we found a significant impact of IGF-I (β = .994, p = .000) and IGF-BP3 (β = -.537, p=.013) on serum FGF23. Among the tested parameters, the most important contribution to FGF23 variations at 12 months was SDS IGF1, followed by IGF1, total FAT, and IGFBP3; in addition, total BMD and BMI also have an important contribution (tab. III).

At the same time, we corroborated the level of FGF23 with the evolution of BMD and BMC. We built a multiple regression model to predict the values of total BMD and BMC at 12 months according to the values of

the following independent variables: vitamin D, PTH, FGF23, total calcium, ionic calcium, and phosphorus. The FGF23 variable, however, is not statistically significant and does not determine a significant variation of the dependent variable (tab. III).

DISCUSSION

Our research is among the forefront to investigate the relationship between FGF23 and bone parameters, respectively, in GHD children. To our knowledge, the impact of FGF23 on bone mineral density has not yet been evaluated in GHD children.

In our study, we investigated the effect of GH substitution treatment on FGF23 serum levels in prepubertal GH-deficient children. We found that the increase in serum phosphate by GH therapy is accompanied by an increase in the phosphaturic FGF23 levels. Numerous studies in children and adults with GHD have presented similar results on phosphate metabolism during GH substitution therapy (9, 11, 16).

Knowledge of the disorders of phosphate homeostasis and studies of FGF23 have uncovered a bone-kidney axis and new systems of biology that govern bone mineralization, extremely important for normal linear growth.

Apart from the crucial role of promoting linear growth, GH has various metabolic effects, influencing body composition, muscle mass, adipose, and osseous tissue. Achieving and maintaining a normal peak bone mass during childhood and adolescence is important for preventing osteoporosis later in life. GH/IGF1 axis interacts with the bone-forming unit, and it has a positive effect on bone formation (3, 4, 5, 6).

FGF23, predominantly produced by osteocytes, is the principal phosphaturic factor in the bone-kidney axis, coordinating systemic phosphate homeostasis with skeletal mineralization. FGF23 is catabolized into

two active fragments, the N-terminal peptide that binds to the FGF receptor (FGFR) in the tissues and the C-terminal fragment that binds to Klotho (17). In renal proximal tubular cells, FGF23 binds to the FGFR, requiring a co-receptor, Klotho, a transmembrane protein. FGF23's primary function is to maintain normal serum phosphate concentration, promoting renal phosphate wasting and inhibition of the 1α-hydroxylase activity, downregulating the production of calcitriol (18). The net effect of both hormonal actions is to lower serum phosphate concentration. Furthermore, an intact FGF23 axis is important for normal linear growth. This becomes obvious in human genetic disorders with an excess of FGF23 (hypophosphatemic rickets) where linear growth is impaired (19).

There are only a few studies in the literature (2, 8, 11, 20) that have identified a connection between the GH/IGF1 system and the FGF23/Klotho system. Although their actions are contradictory, with opposite effects on phosphorus metabolism, both systems are crucial for linear growth and bone mineralization (21, 22). The actual interplay between them is not yet fully elucidated. The FGF23 system negatively regulates phosphate, having an overall harmful impact on bone metabolism. The FGF23/ Klotho complex blocks the Wnt bone formation signaling pathway, while FGF23 has an additive effect to that of PTH upon bone resorption (23). In this context, one may assume that GH/IGF1 axis increases serum phosphate by the suppression of the FGF23 system. However, our data, along with the results of other studies (2, 8, 11) show that the increase in serum phosphate by GH is not mediated through the suppression of the phosphaturic FGF23 system.

Our finding of a positive correlation between serum phosphate and FGF23 in children with GHD is also found in healthy children (1). This could indicate a counterregulatory mechanism between serum phosphate and FGF23, so that, when the level of phosphorus in the blood begins to increase (secondary to diet, reduced phosphate excretion by the kidneys, or in our case GH substitution treatment), FGF23 also begins to increase to maintain the PO4 levels within normal values (1). GH treatment might be the trigger factor for the elevation of FGF23 as a feedback mechanism, to maintain serum phosphate homeostasis (2). Also, the interaction between GH and FGF23 might be mediated via the activation of the renal 1-alpha-hydroxylase - upregulated by GH and downregulated by FGF23 (7, 23). Indeed, data in the literature indicate a relationship between GH/IGF-I axis with the FGF23/Klotho pathway in neonates (20), healthy patients (1), GHD children (2, 8), or patients with acromegaly (11).

In patients with acromegaly FGF23 levels are elevated and return to normal levels postoperatively (11), whereas rhGH treatment in GHD children causes a significant increase of cFGF23 (2), like our study. Therefore, the study of acromegaly patients demonstrated that the detected hyperphosphatemia is not caused by deficient FGF23 action (11). The mechanisms and pathways of interaction between these systems have not been fully elucidated so far. One could hypothesize that the effect of GH treatment on phosphate metabolism is mediated by another mechanism, such as a direct antiphosphaturic effect of the GH/IGF1 axis which is well-supported in the study of Efthymiadou A *et al*, by demonstrating a positive correlation of serum IGF1 with the ratio of the maximum rate of renal tubular reabsorption of phosphate to glomerular filtration rate (TmPO4/GFR) (2).

Our results are consistent with the ones

reported in two other previous studies. One of the reports measured only plasma cFGF23 levels (8), as we did in our series of patients. Despite the higher doses of GH used in Gardner *et al* study, the magnitude of cFGF23 rise was similar, indicating that the GH effect on cFGF23 is not dose dependent. The level of cFGF23 tended to increase, even after adjusting for age, sex, total calcium, and phosphorus (8). This is an unanticipated observation, given the role of FGF23 as phosphaturic factor. Thus, the increase in FGF23 may be the counterregulatory effect of GH therapy. Efthymiadou A *et al*, had a more intergraded approach, measuring cFGF23, iFGF23, and Klotho, but found similar results for FGF23 variations during GH treatment (2). From all three studies, we can state that the effect of GH therapy on FGF23 levels is present from the 3rd month of GH therapy (2), persisted during the 8th month (8), and lasts at least until the 12th month -as seen in our study- but is unknown how early it appears and whether is sustained as long as GH treatment lasts.

Data in the literature support this relationship of IGF1 with the FGF23/Klotho axis in healthy and in short-stature children with or without GH deficiency (24). We suggest that GH replacement therapy interacts with the FGF23/Klotho axis as a feedback mechanism for the maintenance of phosphate homeostasis.

In agreement with other authors (2), we found a positive association between SDS Height with IGF1, but more interestingly, SDS Height was also strongly associated with FGF23 levels. This aspect was also found in normal healthy children (1, 25), emphasizing the fact that phosphate homeostasis is essential for linear growth and appropriate mineralization of the growth plate; therefore, an intact FGF23 axis is important. Thus, the positive relationship we found between FGF23, height SDS, and IGF1 most likely reflects the significance of FGF23 actions on linear growth, with the rise in FGF23 rather than mirroring the GH and IGF1 effects.

The observed loss in BMD found in patients with isolated GHD as well as in those with multiple pituitary deficiencies, suggests that GHD might be the essential factor predicting low BMD (21). Previous observational studies have indicated that elevated levels of FGF23, by inhibition of calcitriol synthesis, could lead to mineralization damage and a lack of ossification in cartilage (26). In mice models, FGF23 leads to growth retardation, and overexpression of FGF23 can also inhibit osteoblast differentiation and cause matrix mineralization in cells (27). The association between FGF23 and body composition parameters, with BMD and BMC, may suggest a direct effect of the FGF23 on obtaining and maintaining an adequate BMD. Data in the literature are scarce and FGF23 has mainly been determined in conditions of bone metabolic disorders (hypophosphatemic rickets), tumor-induced osteomalacia, and in children with chronic renal failure and kidney disease, with contradictory results. Moreover, the fact that different assays are used to determine FGF23 levels (cFGF23 and / or iFGF23) could contribute to conflicting results.

In some studies, the serum level of FGF-23 was not correlated with a change in BMD in maintenance hemodialysis patients (28) or in bone diseases (30), while El-Hodhod *et al* (22) found that FGF23 contributes to low BMD in childhood inflammatory bowel disease. Wang *et al* (13) study suggests that there may be a causal relationship between FGF23 levels and BMD of the heel and femoral neck in adults. A large retrospective

study has suggested that a high concentration of FGF23 is associated with a low BMD of the hip in the elderly population (30). FGF23 was negatively and independently associated with BMD and/or BMC and contributed to up to 10% of femoral neck BMD variance in postmenopausal women in the study of Bilha S *et al.* (12). Mirza *et al.* concluded that when the serum FGF23 concentration was higher than 55.7 pg/mL, the risk of hip and non-vertebral fractures was significantly increased in elderly men (14). In our study, we found a positive correlation between FGF23 and total and lumbar BMD, but no true impact of FGF23 concentration variations on ΔBMD in multiple regression analysis. It is probably the effect of IGF1 upon linear growth that outweighs the effect of other potential regulators.

Our study is limited by the small number of patients included, the lack of urinary phosphate excretion assessment, and the period of assessment of only 12 months. However, to our knowledge, our study is the first to investigate the impact of FGF23 on BMD/BMC in GHD children during replacement rhGH therapy. Further studies are necessary to reveal the complex interplay of these factors.

CONCLUSIONS

Although our understanding of phosphate homeostasis has been dramatically increased from previous studies, the role of FGF23 during GH replacement therapy is not fully elucidated and data are limited. An intact FGF23 and GH/IGF1 axis are essential for linear growth, to achieve appropriate mineralization of the growth plate and maintained normal phosphate homeostasis. GHD children present with an increase in serum phosphate during GH therapy - not a result of the suppression, but rather with upregulation of the phosphaturic FGF23. The association of FGF23 with height SDS and IGF1 could indicate complex underlying interactions between GH/IGF1 and FGF23/Klotho axis to promote growth. This study did not find a causal relationship between FGF23 levels and BMD/BMC in GHD children; however, more studies are necessary to determine whether FGF23 rather mirrors the effects of GH/IGF1 upon calcium, phosphate, and bone homeostasis, or is truly a player in the homeostasis of growth.

NEWS

LEFT ATRIAL APPENDAGE CLOSURE VERSUS NON-WARFARIN ORAL ANTICOAGULATION: WHO WILL WIN?

Atrial fibrillation (AF) is a common arrhythmia that is associated with substantial morbidity and mortality, particularly due to stroke and thromboembolism. Left atrial appendage closure (LAAC) is a non-pharmacological option for preventing cardioembolic events in patients with AF. Since treatment using non-warfarin oral anticoagulants is associated with less bleeding than warfarin, the potential benefit of LAAC relative to NOAC is unclear, prompting the PRAGUE-17 trial. Between 2015 and 2019, 201 patients were randomized per group, and followed for a median of 3.5 year in the LAAC group, and 3.5 years in the NOAC group. LAAC was non-inferior to NOAC for the primary endpoint outcome. There were also no significant differences between groups for all-stroke/TIA, clinically relevant bleeding or cardiovascular mortality. However, for non-procedural and device-related events, LAAC was associated with a significantly reduced rate of clinically-relevant bleeding. Among non-valvular patients with AF and at high risk for stroke and bleeding, the non-inferiority of LAAC to NOAC relative to the composite of cardioembolic events, CV death, significant procedure/device-related complications, or clinically-relevant bleeding, was maintained during long-term follow-up. (Osmancik P, Herman D, Neuzil P, *et al.* Left Atrial Appendage Closure versus Non-Warfarin Oral Anticoagulation in Atrial Fibrillation: 4-Year Outcomes of PRAGUE-17. *J Am Coll Cardiol* 2021; 78(19): e157 / doi: 10.1016/ j.jacc. 2021.10.023).

ASSESSING THE RESILIENCE OF HEALTHCARE PROFESSIONALS IN A ROMANIAN EMERGENCY UNIT DURING THE COVID-19 PANDEMIC

ASSESSING THE RESILIENCE OF HEALTHCARE PROFESSIONALS IN A ROMANIAN EMERGENCY UNIT DURING THE COVID-19 PANDEMIC (Abstract): Worldwide, during COVID-19 pandemic, the healthcare professionals have been exposed to professional and existential stress. The **aims** of this study were to evaluate of the emotional impact, the degree of resilience of medical staff, immediately after exposure to the risk of COVID-19. **Material and methods**: e enrolled 64 participants (30 doctors and 34 nurses), from the Emergency Department of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi. Each participant completed a self-report 63 items questionnaire. Self-perceived stress, depression symptoms, anxiety symptoms were measured in our research. *SPSS 27.0* software was used for data analysis. **Results:** We have identified statistically significant difference between medical doctors and nursed regarding the possibility of managing the critical situation at the workplace and the difficulty understanding the situation at workplace. Sleep quality, positive emotions and life satisfaction need to be improved to increase the psychological resilience of healthcare professionals working during the COVID-19 pandemic. **Conclusions:** Doctors constitute the group with the lowest levels of psychological resilience among health care workers. This study confirms the need to improve positive emotions and weaken negative emotions of healthcare professionals. **Keywords:** RESILIENCE, EMOTIONAL WELL-BEING, SARS-CoV-2, PANDEMIC.

COVID-9 pandemic has spread worldwide and is an important global public health issue as on 3rd of February 2023, there have been 754,018,841 confirmed cases of COVID-19 in the world, including 6,817,478 deaths, reported to WHO. In Romania there have been 3,325,006 confirmed cases of COVID-19 with 67,576 deaths, reported to WHO. As of 21st of January 2023, a total of 16,102,916 vaccine doses have been administered (1).

The coronavirus SARS-CoV-2, the etiologic agent of COVID-19, is studied by many research groups, worldwide. One of the most recent papers published in Nature journal is referring to guanosine-specific

pocket in the essential NiRAN domain that could be optimized as a therapeutic target to treat new coronaviral borne diseases (2). A multidisciplinary team confirmed the short-term effectiveness of actual vaccines (the mRNA or inactivated vaccine in preventing SARS-CoV-2 Omicron BA.2 infection), and at the same time the authors underlined the need of updated studies according to fast viral evolution, to develop new vaccination strategies (3).

Medical staff, both physicians and nurses from emergency medicine have been deeply involved in the COVID-9 pandemic, in diagnosis, therapy, follow-up, and vaccination campaigns. A recent paper identified some challenges and opportunities for medical staff, recommending that learning should be used by health care professionals to promote and restore health and to improve the lives and wellbeing of individuals, families, and communities, and at the same time, the authors recommended to successfully live their own lives, to balance work and other activities, and to preserve a sense of purpose, service, and mental vitality. Maintaining the values of health-care professions is a crucial goal for health educators and for optimal management of a pandemic (4).

Using the keywords *resilience among medical staff*, we identified 161 papers published in the last year, which underlines that this topic is of high importance in medical field, from which we have selected the most representative studies. In a very recent cross-sectional study (March 2023) which involved 602 medical staff from Beijing, it was identified that resilience and self-esteem was a mediator between depression and burnout (Hao *et al.*, 2023). A 2-year observational study during COVID-19 pandemic realized in Taiwan, identified poor sleep, lack of exercise, long working hours, and being nursing staff as risk factors regarding an increase in personal burnout, and depression among health care professionals Chu *et al*., 2023). A descriptive phenomenological study published in Lancet, performed on an important number of public health workers, university staff, and hospital administrators from Philippines, identified stress and mental health exhaustion, fear of infection during service provision after the initial wave of the COVID-19 pandemic (Maravilla *et al*., 2022). Russell *et al*. conducted a study in Australia which referred to key pandemic-generated modifications to safety, clinical, workflow and practice management routines, as procedures to reduce infectious disease transmission (e.g., *staff-to-staff contact reduced greatly*), procedures for conducting consultations via phone or video, rather than face to face (e.g., *most GPs provided telehealth from the practice, but some worked from home when isolating or unwell*). The authors considered that their study was a natural experiment of the resilience of primary care in Australia (Russell *et al*., 2023).

Starting from definition of Mallak *et al*., which stated in 1998 that resilience is *the human capacity to adapt in the face of difficulty and ongoing significant life stressors* (Mallak *et al*., 1998), authors from Germany aimed to explore to what extent can critical care staff use their spirituality by themselves to reduce moral distress and strengthen their resilience. After a comprehensive analysis of 13 studies (e.g., spirituality as moral distress, spirituality as strategy, spiritual resources support, and influence of spirituality on resilience), the authors concluded that spirituality is not sufficient to develop the confi-

dence to cope with ethically critical situations, and more important is that critical care staff to be supported by their institution to reflect on their work, and to find meaning in their care. Researchers from Netherland conducted a study in an elite university hospital, analyzing how the infection prevention staff managed the scarcities emerging at the onset of the COVID-19 pandemic. The authors identified that defining safety, anticipating scarcity, and tinkering with quality could be a modality to enable a resilient response to infection prevention. Also important for these authors is updating Infection prevention guidelines for managing the emerging crisis (Bal *et al*., 2022). Similar studies have been performed in other region of the world as in Tunisia (in which the authors identified that self-reported resilience, work engagement, and burnout were the predictors of compassion satisfaction, in cross-sectional study among heath care givers caring for confirmed and suspected COVID-19 patients, through a self-administrated questionnaire) or in Saudi Arabia (in which the authors aimed to evaluate the relationship between the resilience and emotional intelligence of nurses during the COVID-19 pandemic, and they identified nationality, ward assignment, years of experience as having significant relationships with emotional intelligence). These studies concluded that there is a need for more resilience promoting interventions to be implemented for achieving psychological well-being needs of the nurses. Also, there is a need for improving emotional-intelligence skills of assisting nurses during pandemic outbreaks, and therefore emotional intelligence should be integrated into decision-making (Omri *et al*., 2022, Aljarboa *et al*., 2022). Researchers from New York evaluated mental health among Emergency Department healthcare workers in one cross-sectional study, which involved 247 health care workers. The authors found significant difference between clinical *vs.* non-clinical health care workers for psychological distress symptom burden, depression, and perceived stress. The authors considered that is necessary to maintain mental well-being of nurses and medical doctors, this being crucial for optimally functioning healthcare systems (Gustafson *et al*., 2022).

As the well-being and emotional resilience of health care professionals are essential components of continued health care services during the COVID-19 pandemic, health professionals have been observed during pandemic to have serious psychological problems, having the risk of being exposed to problems in terms of mental health (15). The well-being and emotional resilience of healthcare workers were critical components of continuing healthcare services during the COVID-19 pandemic. Thus, it is essential to anticipate the stress related to this process and to provide adequate medical assistance. Important follow-up and assessment of health workers' well-being is in terms of ensuring their successful reintegration with their colleagues.

Aims of this study were to evaluate of the emotional impact, the degree of stress of the medical staff from an Emergency Department (ED), of both doctors and medical nurses, exposed to the risk of getting infected with COVID-19, through emergency diagnosis and treatment of suspected and confirmed positive patients during 2020.

MATERIAL AND METHODS

In the period 15.11-30.11.2020, we have applied in the ED of the "Sf. Spiri-

don" County Clinical Emergency Hospital Iasi, one questionnaire based on 2 scales present in the specialized literature, described in details bellow:

a. *Brief Resilience Scale (BRS)*. The scale was developed by B. Smith *et al*. (5) to measure individual psychological resilience. It consists of six items (three reversed questions) measured on a 5-point scale (1 Never appropriate and 5 Completely appropriate). The total range of scores was between 6 and 30. Higher scores on the scale indicate a higher level of psychological resilience. The Turkish version of the scale was adapted by Dogan (2015). The adapted scale was highly sufficient in terms of CFA values (v2/ df (12.86 / 7) ¼ 1.83, NFI ¼ 0.99, CFI ¼ 0 .99, GFI ¼ 0.99, SRMR ¼ 0.03, RMSEA ¼ 0.05) and internal consistency coefficient (¼ .88).

b. *Scale related to life satisfaction (SMV)*. The SMV consists of five items measured on a 7-point Likert scale (1: Strongly disagree, 7: Strongly agree). It was developed by Diener *et al*. (1985) and adapted by de Koker (6). Higher scores on the scale indicate higher levels of life satisfaction. We have used the Romanian translated versions of above descripted scales in our 63 items self-questionnaires.

The questionnaire included 63 items and we observed that in addition to the 2 scales consecrated in the literature, the applied questionnaire also contains other relevant items for the emotional impact among the personnel in the study. The number of distributed questionnaires was 70, of which 64 were validated to be interpreted, the latter were statistically processed in this study. The survey was based on the questionnaire that was physically distributed to the staff from the emergency reception service (doctors and nurses). Participants were informed about the aims of the study and the research procedures. No reward was offered for participation. No personally identifiable information was requested.

This study had received the ethical approval of the host-hospital and the study participants have been informed and they signed the ethical consent prepared by the PI of this study.

Statistical analysis. Data processing was performed using *SPSS 27.0* package software. The method used was the *Spearman rank correlation coefficient p* (rho), which is a coefficient based on ranks, it is not influenced by the representativeness of the average, and it is generally used when the research group is small, or when at least one of the variables does not meet the administration conditions of the parametric tests. This indicator is frequently used in social and human sciences.

RESULTS

The questionnaire was applied to 64 persons, 30 doctors (M:F ratio 0.50) and 34 nurses (M:F ratio 0.4782). The age distribution was on average 38.13 years for doctors (66.67% women) and 36.47 years for nurses (67.64% women), and the average age for the whole group is 37.25 years. Out of a total of 64 people, 32.81% were infected with COVID-19, 56.25% were not infected, and 10.93% did not know if they had the virus. These data were obtained from the first 6 items of the questionnaire.

The items 7-15 were referring to a list of statements regarding concerns regarding COVID-19. The *degree of concern about COVID-19*: we note that from the category of doctors 50% are very concerned and 33.33% are concerned, and from the nurses group the results were 44.11% / 26.47% for

very concerned / concerned. Only a percentage of 3.12% is very little concerned about COVID-19. Item 10 was referring at the *virus capacity of spreading*: 50% of persons believed that the COVID-19 virus spreads a lot and only 1.56% think that it spreads very little. Item 11 asked the opinion of medical staff regarding *the access to information about the COVID-19 virus*: 56.25% consider that they have access to a lot of information, 26.6% consider that they have high access and 17.2% consider that they have medium access to information. Item 12 - *worry about contacting the virus* - 45.3% were very worried, 26.6% were worried, 14.1% average and a percentage of 6.3% were very little worried. Here we observed differences between the two categories: doctors are much more worried, as no doctor showed very little concern, while 11.8% of nurses think they are not worried about the COVID-19 virus. Item 13 – *threat*: 29.7% believed that the threat of COVID-19 influences them to be around people and 15.6% do not feel threatened. We observe differences between the two categories: doctors feel less threatened 20.6%, among doctors they consider themselves very little threatened compared to nurses, only 10% consider themselves very little threatened. 56.25% of study participants considered themselves very much threatened regarding travel plans, while only 7.81% consider themselves very little threatened. There are small differences between the two categories, 60% of doctors consider themselves threatened and 52.6% of nurses. *The influence of the threat of safety measures* was considered by 60% of the medical subjects, which believed that the infection with COVID-19 greatly influenced them in the use of safety measures, while the nurses subjects in percentage of 56.3%.

From item 16 to item 24 we applied a set of questions regarding how often the subjects were disturbed in the last 2 weeks in carrying out activities: *low interest in certain things, feeling depressed, sleep problems, feeling tired, appetite, fear of failure, concentration problems, slowness in activities or restlessness, thoughts of death or injury*. 56.66% of the doctors stated that they had low interest in carrying out the activities for only a few days *versus* the nurses which answered in percentage of 26.47%. Depression was recognized by 53.33% of the doctors, which felt depressed for a few days, and 29.41% of the nurses. We observed differences between the two categories of subjects, regarding sleeping problems: 20.58% of nurses complained of sleep problems almost every day, while 6.67% of doctors. 20.31% of all the subjects complained of feeling fatigue almost every day. 63.33% of the responding doctors do not accuse slowness or restlessness at all, 23.33% accuse a few days a week, 10% more than half of the days of the week and 3.33% almost every day. Among nurses respondents, the percentages are 61.76% not at all, 23.52% a few days, 8.82% more than half of the days of the week and 5.88% almost every day. The total percentage is 62.50% for not at all, 23.43% a few days, 9.37% more than half of the days of the week and 4.68% almost every day. When asked about the presence of thoughts related to death or injury, 90.62% of the respondents declared that they did not have such thoughts at all, and only 2.94% and 5.88% of the nurses declared that they had such thoughts in more than half of the days or almost daily. The percentage among doctors was 0% for this item.

The average response to *the fear of in-*

fection was 6.07 among doctors and 5.32 among nurses. Regarding *the stressful work environment*, the answers were approximately identical in the two categories, with an average of 6.17 for doctors and 6.06 for nurses.

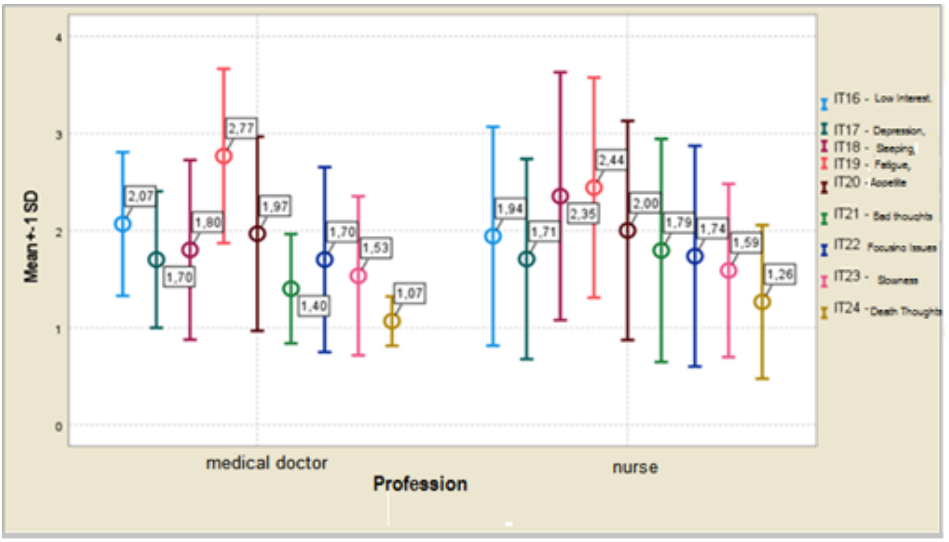

Fig. 1. Comparison between physicians and nurses regarding *low interest, depression, sleeping, fatigue, appetite, focusing issues* and *death thoughts.*

For the *presence of problems at the workplace*, the respondents declared the following related to involuntary thoughts about the workplace: 34.37% not at all, 50% moderately and only 15.63% or thinking about them extremely much. Regarding the *persistence or the feeling of being followed by problems at work*, a significant difference can be observed between doctors and nurses, 33.33% of doctors do not feel followed at all, and only 23.52% of nurses claims this thing. For the answer given to the item referring to *other things that triggered thoughts related to work*, 35.93% do not blame this fact, 50% a little and 14.06% blame this very much, the percentages are close. Feelings related to the workplace were described as extremely present by 12.50% of respondents, moderately present by 50%, with notable differences between doctors 60% and nurses 41.17% and not at all present by 37.50% of respondents. 70% of doctors and 52.94% of nurses moderately described *the need to think about problems after leaving the workplace*, 31.25% not at all and 7.81% of respondents do not think to problems at the workplace extremely much, without significant differences among the two categories of personnel. 10.93% of the respondents accused *concentration problems* extremely, 40.62% moderately, with large differences between doctors 53.33% and nurses 29.41% and not at all 48.4%, also with significant differences between doctors 36.67% and nurses 58.82%.

For the question *I totally agree with the possibility of managing the situation at work*, only 20% of the doctors answered affirmatively, unlike 44.11% of the nurses. Here a direct, statistically significant corre-

lation was also identified (p=0.047) between the professional degree and the agreement with the statement in the analyzed item. The *difficulty of understanding the situation at the workplace* reveals significant differences between the two professional categories, doctors considering the situation at the workplace more difficult to understand compared to nurses (6.7%+30% compared to 11.8%+5.9%). A statistically significant correlation (p = 0.008) was identified between occupational level and agreement with this statement in the item. Most respondents consider the *workplace structured*, respectively 26.56%, and the majority also consider the current workplace easy to influence, in a percentage of 20.31%. Many of the respondents, 17.18% mentioned total agreement and 17.18% strong agreement, consider the *work environment controllable*. Most respondents, 25%, consider *the current job attractive from a financial point of view*, and thy are neutral regarding the predictability of the current job, respectively 20.3%+21.9%+12.5%. The majority of respondents, in percentage of 57.81%, believe that they *can adapt extremely easily to the changes occurring at the workplace* and that they can quickly overcome unforeseen situations occurring at the workplace. The respondents, in an overwhelming percentage, *try to see a happy side in the event of problems*, to overcome them successfully, the percentage being 36.67%. Most respondents believe that *exposure to stress makes them stronger*, 34.37% agreeing with this statement. 43.75% of the respondents say that they recover quickly after the illness. The majority of respondents, in percentage of 53.12%, believe that they can easily overcome the obstacles in order to achieve the objectives at the workplace. Most of the surveyed staff (75%) declared *that under pressure they can stay focused and think clearly*, without identifying major differences between doctors and nurses (76.67% *vs.* 73.52%). In proportion to 75% of the medical personnel declared that it is not easy to be discouraged in the face of a failure (73.34% doctors *vs.* 76.47% nurses). Regarding the *perception of one's own person in terms of the ability to face challenges and life's difficulties*, more than half of the surveyed staff (56.3%) believe that it is a valid statement in all situations, there being no differences between doctors and nurses (56.7% *vs.* 55.9%). *Unpleasant or painful feelings such as sadness, fear and anger are easy to manage* for 84.4% of the medical staff, with a slightly higher proportion in the case of doctors (90%) compared to nurses (79.4%), the difference which is not but statistically significant. In the proportion of 59.4%, *medical personnel consider themselves less susceptible to colds, flu, and other infectious diseases*, with no differences between doctors and nurses. However, only 48.43% consider that it is unlikely that they will catch a cold, flu or other diseases when they manifest themselves in people around them (43.33% of doctor's *vs.* 52.94% of nurses, without being a statistically significant difference was identified). In accordance with the previously identified data, 75% of the surveyed staff believe that the risk of developing an infectious disease that exists in the people around them is low (80% doctors *vs.* 70.58% nurses, without identifying a statistically significant difference between them). 65.62% partially agree with the fact that they have an immune system that can protect them from most diseases that those around them have, without differences

between doctors and nurses, agreeing with the following statement regarding the possibility of doing an infectious disease to those around them (68.75% disagree). 51.56% partially agree with the fact that considering past experiences, the chances of getting sick are low even when friends are sick, without identifying differences between doctors and nurses, results found in agreement with the following statement when 46.87% declare that they do not agree at all that they have a history of susceptibility to infectious diseases.

Regarding the ways in which the surveyed medical staff believe that infections can be transmitted, the situations in which those around sneeze without covering their mouths (totally agree 71.87%), the use of used clothing (totally agree 51.56%)), touching money (totally agree 40.62%), staying around sick people (totally agree 31.25%) and less use of public telephones (totally agree 21.87%), using another person's pen (total agree 18.75%), or sharing a bottle of water with a friend (fully agree 15.62%).

DISCUSSION

This study analyzed the emotional impact, the degree of stress of the medical staff of both doctors and medical nurses, exposed to the risk of getting infected with COVID-19. In our study we have identified statistically significant difference between medical doctors and nursed for items referring to the possibility of managing the situation at the workplace (p=0.047) and to difficulty understanding the situation at workplace (p=0.008).Using the Spearman correlation coefficient, we identified that most of the correlations are positive, or directly proportional. We marked the statistically significant correlations in the first table, and we have used color codes for their intensity: yellow – weak correlations, below 0.3, orange – moderate correlations, between 0.3 – 0.5 and red – strong correlations, between 0.5 – 1.00. Item 25A (*fear of infection*) is moderately to strongly and statistically significantly correlated with the following questionnaire items: IT 13 (*threat*) – rho = 0.487, IT18 (*sleeping*) – rho = 0.406, IT 26 (*thinking*) – rho = 0.464, IT 28 (*other things*) – rho = 0.410, IT30 (*not thinking*) – rho = 0.422 and IT31 (*concentration problems*) – rho = 0.494.

The correlations recorded are directly proportional or positive, which means that the fear of infection is the greater, as the subjects indicated higher scores on the mentioned items.

Correlations were also statistically significant, directly proportional, moderate, but weaker in intensity and with items 7, 14, 19, 20, 22 and 34; the correlation with item number 43 (*I recover quickly after illness*) also belongs to the same category of intensity, but in this case the correlation changes its meaning, being inversely proportional – the subject's fear of infection is all the more pronounced the more they appreciate that the time of their recovery after an episode of illness is longer. Also, we observed statistically significant correlations, but weaker in intensity and still directly proportional, of item 25A with items 8, 16, 23, 29, 32, 57 and 58.

Item 25B (*stressful work*) is in turn statistically significantly, directly proportionally and moderately to strongly correlated with IT18 (*sleep*) – rho = 0.421, IT19 (*fatigue*) – rho = 0.445, IT20 (*appetite*) – rho = 0.418, IT26 (*thinking*) – rho = 0.441 and IT31 (*concentration problems*) – rho = 0.410 – which means that the subjects note a higher level of stress as they indicated

higher scores on the mentioned questions. There is also a moderate to strong, but inversely proportional, correlation of the stress level with question IT43 (*I recover quickly after illness*) – rho = – 0.480, respectively with high scores on this question. It can thus be stated that, when the subjects consider that it is difficult to recover from the illness, they are moderately afraid of infection, but have a higher level of stress in carrying out their professional activity. Also, the stress level of the subjects is correlated statistically significantly and directly proportionally, but moderately, with items 13 (to a lesser extent, therefore, than in the case of fear of infection), 16, 23, 32, 34 (stronger than in the case of fear of infection), 22 (similar in intensity to the case of fear of infection), and in addition with items 17, 24 and 49. We also observed a moderate correlation, statistically significant but inversely proportional, with item 42 (*stress makes me stronger*) – rho = – 0.314 – so the study subjects perceive a high level of stress at work, but do not consider the stress to make them stronger, and therefore do not motivate them positively. Some positive correlations were also observed, statistically significant but weak in intensity, with items 8, 9, 51, 55 (new correlations), 28, 30 (*much weaker than in the case of fear of infection*) and 57, 58 (*correlations similar in intensity to those in the case of the fear of infection*). In addition, the level of stress is weakly correlated, statistically significant but inversely proportional to item 41 (*I try to see humor*) – rho = -0.262.

The findings of this study showed that in order to increase the psychological resilience of healthcare professionals working during the COVID-19 pandemic, there is a need to improve their sleep quality, positive emotions and life satisfaction. Levels of psychological resilience of healthcare workers in recent years have been found to be higher. Still, doctors constitute the group with the lowest levels of psychological resilience among health workers. We consider that the current study could bring some contribution to the specialized literature in this regard. Primary needs such as sleep, which are the determinants of quality of life, life satisfaction and psychological resilience should be met.

The resilience and well-being of medical staff is a subject of interest for researchers from all continents: USA (Ross *et al*., 2023), Korea (Lee *et al*., 2022), Italy (Giusti *et al*, 2022), Australia (Unjai *et al*., 2022). In these studies, the most frequent answers of medical staff were for high stress, were afraid, different levels of anxiety or depression, work overload, depressive symptoms (7–10). Researchers from Oxford, United Kingdom recognized that resilience-building programs can provide support for staff who endure highly stressful environments and can optimize resilience. In their pilot study, the authors have seen that the study participants – nurses accepted the idea of implementing web-based resilience programs, for optimizing resilience, psychological health, and communication at workplace (Henshall *et al*., 2023).

Haugland *et al.* is sustaining our findings, regarding the need for improving resilience in nurse's category and this should be an ongoing effort (Haugland *et al*, 2023).

The strength of our study is that, for our knowledge, it is one of the first studies in our country which is assessing the resilience and satisfaction with life among medical staff (doctors and nurses).

The limitation of the study is the relatively small number of participants which provided data. Another limitation is that the study participants belong from a single-based unit hospital research and the results cannot be generalized for doctors/nurses working in emergency unit in general. Also, this was a single cross-sectional study with only self-reported measurements of the participants, and improper pre-set demographic variables.

Future studies may reveal more extensive results by collecting data from a larger number of healthcare professionals. Given that the current study is an example of cross-sectional research, there is a need to conduct longitudinal studies that examine the long-term effects of the pandemic. Positive and negative emotions were found to play a significant role in the model as variables that predict the psychological resilience of health workers after the analysis. Therefore, further studies can have a better understanding of the issue by investigating the determinants of positive and negative emotions of healthcare workers during the COVID-19 pandemic. We intend that following this study, to extend the research to a larger number of personnel from the emergency services (and in other EDs in the country), as well as to the people from the ISU services, involved in emergency interventions, in order to obtain much more conclusive data regarding the stress, the behavior in general of the workers from the UPU and ISU emergency services during the COVID-19 pandemic.

CONCLUSIONS

The results of our study showed that to increase the psychological resilience of healthcare professionals working during the

COVID-19 pandemic, their sleep quality, positive emotions and life satisfaction need to be improved. Levels of psychological resilience in healthcare workers in recent years have been higher. On the other hand, higher levels of negative emotions lower the level of psychological resilience. Doctors constitute the group with the lowest levels of psychological resilience among health workers. The research results revealed a significant part of the variables that impact on the psychological resilience of healthcare workers, so that they can provide better services during COVID-19 and similar pandemics. The result of the current study showed that one of the main needs such as: sleep quality, life satisfaction and positive-negative things are part of an important prediction for the psychological resilience of medical professionals.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

THE ROLE OF MAXILLARY SINUS VOLUMETRY IN CHILDREN WITH OBSTRUCTIVE SLEEP APNEA (Abstract): **Aim**: Obstructive sleep apnea (OSA) is a common sleep disorder that can also affect children and represents a risk factor for childhood developmental problems. The aim of this study was to demonstrate if there is a correlation between the maxillary sinuses and nasal airway volumes and the presence of OSA in children. **Material and methods**: We retrospectively analyzed 59 patients from which 28 were diagnosed with OSA and 31 were healthy patients. We calculated the total nasal airway volume and maxillary sinuses volume using a open-source software for segmentation from CBCT (cone-beam computed tomography) data. **Results**: There was a significant difference regarding the BMI and the maxillary sinuses volume between the OSA patients and the control group. **Conclusions**: The maxillary sinuses reduced volume can be used as a predictor for OSA in pediatric patients with ages between 12-18 years old. **Keywords**: OBSTRUCTIVE SLEEP APNEA, CHILDREN, MAXILLARY SINUS, AIRWAY VOLUME.

Obstructive sleep apnea (OSA) is a common sleep disorder characterized by repetitive episodes of partial or complete upper airway obstruction during sleep. These episodes lead to disrupted breathing patterns, recurrent awakenings, and diminished oxygen levels in the body. OSA affects a significant portion of the population, with estimates ranging from 9% to 38% in middle-aged adults (1).

Obstructive sleep apnea is not limited to adults; it can also affect children. OSA prevalence in children varies, but estimates suggest it affects around 1-5% of children (2).

OSA in childhood is a strong risk factor for childhood developmental problems. It is closely related to neurobehavioral problems such as attention deficits, hyperactivity, learning disabilities, memory impairment, poor academic performance, and depression (3, 4) and is a risk factor for physical problems such as developmental delays (5), cardiovascular comorbidities (6), metabolic

disorders, and inflammation (7, 8).

The paranasal sinuses, including the maxillary, ethmoid, sphenoid, and frontal sinuses, are air-filled cavities within the skull bones surrounding the nasal passages. These sinuses play a role in reducing skull weight, providing structural support, and regulating air humidity and temperature (9).

Limited research has explored the correlation between pediatric OSA and paranasal sinus volume and understanding the relationship between them has clinical implications. Reduced sinus volume may impact nasal airflow and ventilation, potentially exacerbating OSA

symptoms (10). Additionally, sinus inflammation and infections may further contribute to airway obstruction in individuals with OSA (11).

The aim of this study was to reveal the associations between paranasal sinuses and nasal cavity volume and the presence of OSA in teenagers.

MATERIAL AND METHODS

Study population

This is a retrospective study of 28 patients (13 females and 15 males) aged 12-18 years old, already diagnosed with OSA based on clinical and physical examinations and polysomnography with AHI (apnea-hypopnea index ≥5), sent by the referring physician for a CBCT (cone beam computed tomography) examination at the "Medimagis Imaging Clinic" between March 2020 and December 2022.

The control group consisted of 31 subjects (13 females and 18 males) with ages between 12-18 years old and without any respiratory complaints, with a CBCT examination in the same clinic, in the same period of time.

We excluded patients with chronic or acute rhinosinusitis and allergic rhinitis, cranio-facial abnormalities or history of cranio-facial surgery.

Acquisition and Postprocessing of CBCT (cone-beam computed tomography) Data

The patients were placed in a sitting position with the Frankfurt plane parallel to the floor and the mid-sagittal plane perpendicular to the floor. The patients were told not to move, to avoid swallowing and to keep a regulated breathing interval during acquisition of images.

All included patients had CBCT examination in an interval of 1-3 months after the diagnosis and it was performed by CBCT ProMax 3D Max (Planmeca, Helsinki, Finland) with the largest field of view (FOV) available (502x502x437) with a voxel size of 0.4 mm, tube potential 90 kV, and tube current 10 mA.

Images were then exported in picture archiving and communication system (PACS) in standard DICOM format (digital imaging and communication in medicine). The data was loaded to the segmentation software, 3D Slicer, a free and open-source application for medical image manipulation (12).

The delimitations of the nasal cavity and paranasal sinuses were the following:

-a midsagittal reference plane (MSRP) was defined as a plane passing through nasion (N), anterior nasal spine (ANS), and the posterior nasal spine (PNS);

-the anterior plane was a line passing through external narines;

-the superior border was a plane passing through N, parallel to the palatal plane (that passes through ANS and PNS and is perpendicular to MSRP).

The nasal cavity and paranasal sinuses

were segmented using a threshold method that selected a range of pixels between a predefined interval related to the density of air (-1000 and -400) and the segmented volume was calculated automatically with the software's feature (fig. 1). The right and left maxillary sinuses were separated from the whole nasal airway for volume measurements (fig. 2). The process was done by radiologists.

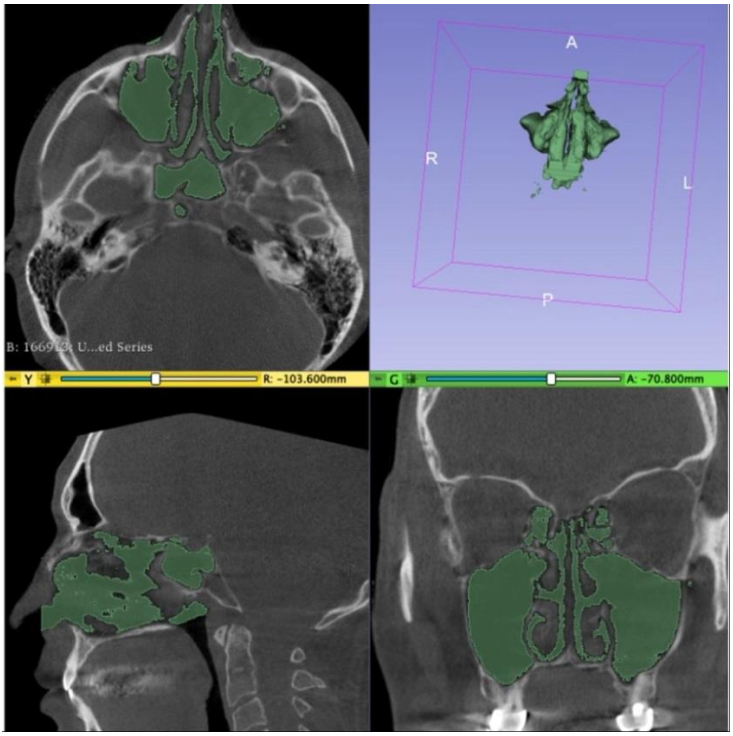

Fig. 1. Nasal airway segmentation using 3D Slicer.

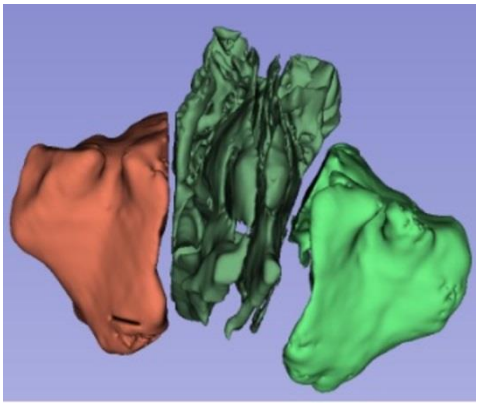

Fig. 2. Right and left maxillary sinuses separated from the rest of the nasal airway using 3D Slicer software

Statistical analysis

Statistical significance was established at a *p*-value below 0.05. Statistical analysis was performed using *SPSS* (IBM SPSS Statistics, release 24.0, Armonk, New York, NY, USA).

RESULTS

The descriptive statistics of control and OSA patients groups are displayed in Table I.

TABLE I.

Descriptive statistics of group 0 (control group) and group 1 (OSA patients).

	Age	BMI (body mass index)	Total nasal airway volume (cm3)	Maxillary sinuses volume (cm3)	Sinus/nasal airway ratio (%)
Group 0 (control)	15.06 ± 1.98	24.09 ± 3.99	84.58 ± 10.69	49.48 ± 3.54	59.57 ± 9.85
Group 1 (OSA patients)	15.39 ± 1.85	27.18 ± 1.77	82.05 ± 6.95	42.38 ± 3.29	51.83 ± 3.9
p-value	0.529	<0.001	0.268	<0.001	0.002

There was no significant differences between age or sex but there was significant differences in BMI index between the groups.

No significant difference between the volumes of total nasal airway in the two groups was found. The maxillary sinuses volume and the ratio to the total nasal airway was significantly reduced in patients with OSA compared to control group.

DISCUSSION

In this study we analyzed the correlation between the nasal airway volume, maxillary sinuses and the presence of OSA in pediatric patients above 12 years old. We found that that children with OSA had significantly smaller maxillary sinus volumes compared to the control group. Therefore, it may be said that decreased maxillary sinus volume can be a predictor of OSA development but not necessarily an exacerbating factor. Kim YJ *et al.* (13) conducted a study on 109 adult patients with OSA that underwent overnight polysomnography and CT (computed tomography) of ostiomeatal unit and found that patients with OSA had decreased ratios of maxillary sinus volume to whole nasal airway volume compared with normal subjects. Also, he didn't find any correlation between the volumes of total nasal airway or maxillary sinuses with the severity of OSA. In another study, Rodriguez *et al.* used CT and nasal fiber-optic endoscopy to assess the nasal airway volume and the anatomical changes of nasal cavity in patients with OSA and also found no association between nasal cavity volume and the severity of OSA (14).

Our study focused on pediatric patients between 12 and 18 years old because maxillary sinuses volume increase from postnatal period to adult stage but studies have shown that there isn't a significant size change after the age of 12 years. A study performed by Weiglein *et al.* on Australian cadavers' dried skulls reported that the final size of maxillary sinus is reached at 12 years of age (15). Bhushan B *et al* studied the changes of maxillary sinuses volume with age in children under 18 years old by measuring the height, weight and depth in groups 0-6 years, 6-12 years and

12-18 years using CT. The result showed that there was not a significant increase in maxillary sinus volume in patients older than 12 years old (16).

The majority of studies in the literature that measured the nasal airway volume used medical CT (13), (14), but considering we included in our study children, CBCT used as an imaging method for the nasal airway volume assessment has the advantage of a lower radiation dose and thinner slices that provide a better accuracy. CBCT is a widely used three-dimensional imaging technique and when utilizing a large field of view (FOV) protocol, it becomes a useful diagnostic tool for the upper airway assessment because it is visible in the whole CBCT volume. However, CBCT acquire images with patients in upright position unlike CT machines that require patients to be in supine position. This can be also a limitation of the study as the upright position does not simulate conditions during sleep but also an advantage considering the base of the tongue can protrude in the oropharynx airway and therefor, underestimate the volume of the airway. However, in our study we included only the nasal airway that is not influenced by the supine or upright position.

The ideal method for measuring nasal airflow remains controversial. Because the nasal airway contains not only bony structures but also dynamic ones, such as alar cartilages, turbinate, CT/CBCT images may have some limitations for airway function assessment. These aspect be considered, functional tests like nasal resistance could provide more information about nasal function.

Another aspect that must be discussed is the software used for the segmentation and volume calculation. In this study we used 3D Slicer, an open-source software (12) that has been found to be suitable for segmentation as well as in other studies (17), (18), because it is free and certified for medical use.

The effects of obesity on the development and severity of OSA are well known (19), (20). Our results supported the idea that a high BMI is correlated with the presence of OSA in children.

Nasal inflammatory conditions can also play an important role in the development of OSA (21). In our study we excluded patients with chronic or acute rhinosinusitis and allergic rhinitis in order to have a higher accuracy airway volume but there are studies that report a correlation between nasal obstruction and OSA (11), (22), (23). A survey study in Sweden has shown that respiratory conditions like rhinitis, chronic bronchitis, asthma, were significantly associated with OSA related symptoms (24). A study in Switzerland reported that perennial allergic rhinitis was found in 11% of patients with OSA and in only 2.3% of patients with chronic obstructive pulmonary disease (25). Although the potential mechanisms of the association between OSA and chronic rhinosinusitis are not completely elucidated, a study reported that some nasal inflammatory indicators (number of polymorphonuclear leukocytes, concentrations of bradykinin and the vasoactive intestinal peptide) were significantly higher in patients with OSA than in those without OSA (26). Another study found that chronic intermittent hypoxia due to OSA can determine a release of inflammatory cytokine that may contribute to mucosal and muscular inflammation of the upper airway (27).

Therefore, knowledge of other associated conditions with OSA such as nasal inflammatory diseases is important because it

can either contribute to the pathogenesis of OSA, either decrease the quality of life and the efficiency of CPAP treatment.

CONCLUSIONS

Reduced maxillary sinus volume can be a predictor for obstructive sleep apnea in pediatric patients and understanding the relationship between OSA and paranasal sinus volume has clinical implications. Further research is necessary to explore the underlying mechanisms linking OSA and paranasal sinus volume changes and to investigate potential therapeutic approaches targeting both conditions.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NONTUMORAL PORTAL VEIN THROMBOSIS IN PATIENTS WITH HEPATITIS C VIRUS AND SUSTAINED VIROLOGICAL RESPONSE-A FURTHER CHALLENGING CONSEQUENCE OF LIVER CIRRHOSIS (Abstract): The sustained virologic response (SVR) achieved by most patients treated with direct acting antivirals (DAAs) involves multiple benefits such as regression of fibrosis and improvement in liver function. However, DAAs therapy doesn't eliminate the risk of thrombotic events. The **aim** of our study was to assess the prevalence of nontumoral portal vein thrombosis (PVT) after SVR and identification of risk factors associated with this complication. **Material and methods:** We retrospective analyzed a cohort of patients with HCV-related liver cirrhosis treated with paritaprevir/ritonavir, ombitasvir and dasabuvir (PrOD) ± ribavirin and ledipasvir/sofosbuvir (LED/SOF) ± ribavirin for 12/24 weeks, in a gastroenterology center from Romania, between October 2015 and December 2018. All patients with presumption of PVT were evaluated by abdominal ultrasound and confirmed by CT scan. **Results:** The study included 730 patients treated with DAAs, of which 35 were diagnosed with non-malignant PVT after-SVR (15 men and 20 women, mean age 57.86 ± 7.068 years), corresponding to a prevalence of 4.8%. The mean time from SVR to complication was 290.00 ± 116.639 days. Most patients with non-tumoral PVT after-SVR received LED/SOF (71.4%), while the rest received PrOD (28.6%). Twenty-four patients (68.6%) diagnosed with acute PVT and 11 patients (31.4%) with chronic PVT. During the study, an improvement in liver function was observed, with an improvement in the Child-Pugh and MELD score at the time of SVR; the evolution changes slightly at the 48-week assessment, with a slight increase in the proportion of patients with Child B and MELD ≥ 15. **Conclusions:** Occurrence of non-malignant PVT in patients with HCV-related liver cirrhosis treated with DAAs correspond to the natural evolution of the cirrhotic patient. **Keywords:** CHRONIC HEPATITIS C INFECTION, NONTUMORAL PORTAL VEIN, THROMBOSIS, SUSTAINED VIROLOGICAL RESPONSE, DIRECT-ACTING ANTIVIRALS THERAPY, LIVER CIRRHOSIS.

The sustained virologic response (SVR) achieved by most patients treated with direct-acting antivirals (DAA) involves multiple benefits such as regression of fibrosis, reduction of portal hypertension, and improvement of liver function (1,2). In

addition to the hepatic benefits of the virological cure mentioned, successful eradication of the C virus indirectly leads to the reversal of the hypercoagulable status by lowering procoagulant factors as close to normal parameters as possible, leading to a significant decrease in thrombotic complications (3, 4).

The long-term impact of sustained virological response after direct-acting antivirals on hypercoagulability associated with C viral liver cirrhosis is unknown. Up to this moment, there are few information regarding the improvement of coagulation status in patients treated with antivirals. There is a possibility that the safety profile of direct vascular antivirals may be incorrectly estimated due to the fact that there is no adequate reporting of the actual incidence of arterial and venous thrombotic events in clinical trials. However, an unexpected incidence of portal vein thrombosis (PVT) immediately after treatment with direct antivirals was recently reported (5).

Chronic viral hepatitis C (HCV) is itself associated with an increased risk of thromboembolic complications due to thrombocytopenia, low antithrombin III (ATIII) concentration, and the presence of antiphospholipid antibodies, which predisposes to arterial and venous thrombosis (6). In addition, an increase in platelet aggregation has been observed in patients with chronic HCV infection and advanced fibrosis, a phenomenon that could explain the occurrence of thrombotic events in these patients (6).

The incidence for any type of thromboembolic event reported by Enger *et al.* in a large study was 561.1 per 10,000 person/years in cirrhotic patients and 249.7 per 10,000 person/years for the control group (7). The main thrombotic complications reported in this study that could occur in a cirrhotic patient were deep vein thrombosis, portal vein thrombosis, pulmonary thromboembolism, stroke, and acute coronary syndrome, but most studies focused on non-malignant PVT, which is seen the most frequent.

A reduced number of studies have attempted to evaluate the impact of direct antiviral therapy on coagulation and the main risk factors for the development of thrombotic events in cirrhotic patients treated with direct antivirals and SVR. The majority included thrombotic events such as non-malignant PVT and the one of neoplastic origin that is most often associated with hepatocarcinoma, in which the thrombotic mechanism is different (4,5,8).

The research of Tripodi *et al.* (3) and Russo *et al.* (4), proved for the first time that DAA treatment in patients with C viral liver cirrhosis resulted in improvement of pro- and anticoagulant status in patients who have acquired SVR. It does not substantially alter their balance but makes it more stable and less likely to be disturbed, as was supposed before treatment.

The main suspected risk factor for the occurrence of thrombosis after SVR in these few cases is liver fibrosis, which remains elevated in some of the patients treated with antivirals, a fact that is indirectly reflected on the degree of portal hypertension, mechanisms responsible for venous stasis in port system level with the risk of non-tumoral portal vein (9,10,11).

Thus, this study aimed to evaluate the prevalence of non-malignant portal vein thrombosis in patients with chronic HCV infection treated with interferon-free antivirals, and whether the development of PVT de novo is a reflection of the natural history of cirrhosis in patients with long-

term viral infection or is a consequence of DAA therapy.

MATERIAL AND METHODS

We performed a retrospective study in which we included patients diagnosed with compensated and decompensated viral liver cirrhosis C, randomly selected, to receive treatment with direct antivirals (Ombitasvir/Paritaprevir/Ritonavir + Dasabuvir ± Ribavirin or Sofosbuvir/Ledipasvir ± Ribavirin) for 12/24 weeks, admitted to the Institute of Gastroenterology and Hepatology Iași, Romania, between October 2015 and December 2018. Additionally, they were considered inclusion criteria presence of non-malignant PVT. All patients were clinically and paraclinically evaluated at the time of admission; socio-demographic data, personal antecedents and symptoms were evaluated and recorded for all patients. The diagnosis of cirrhosis was based on clinical, biological and imaging data according to international guidelines. The diagnosis of viral C infection was suspected by anti-HCV Ab positivity and confirmed by HCV-RNA, the detection limit being 15 IU/mL. Sustained virologic response was defined as undetectable HCV-RNA level 12/24 weeks after completion of direct antiviral treatment.

The patients were followed for 3 years, and the data were collected as follows: at the initiation of treatment with direct antivirals (baseline), at the end of antiviral treatment (EOT), 3 months after completion of antiviral treatment (SVR12), 48 weeks after obtaining SVR12, 3 years after obtaining SVR12, on emergency admission in the event of a thrombotic complication after the period of antiviral treatment.

Blood samples for biochemical and immunological evaluations were collected at scheduled visits. At the same time, an additional amount of blood was collected to perform coagulation tests at the time of diagnosis of non-malignant PVT. Two vacutainers of whole blood containing 1/10 volume of sodium citrate as an anticoagulant were taken, each vacutainer having a capacity of 2.7 mL. Blood samples were centrifuged for 15 minutes at 2500xg/min and plasma was collected and stored in 0.5 mL devices and subsequently frozen at -80°C until examination. Processing of biological samples was performed after thawing the plasma at 37°C for 5 minutes.

Portal vein thrombosis was diagnosed using a Philips HD11XE ultrasound machine equipped with a 3.5 MHz convex probe and was confirmed by contrast-enhanced computed tomography. Ultrasound PVT was defined as the presence of hyperechoic material within the portal vein or its branches. The portal cavernoma was defined by the presence of periportal collateral circulation, with the role of short-circuiting the thrombosed area. Portal vein thrombosis was defined as partial if the thrombus occupied less than 90% of the vessel lumen and complete when the thrombus obstructed more than 90% of the vessel. Portal vein thrombosis was considered acute in the context where before the examination the patient showed no signs of PVT, and at the time of diagnosis associated symptoms such as: abdominal pain, onset or worsening of ascites, variceal bleeding, or hepatic encephalopathy.

To check the patients who were a part of our inquiry for liver fibrosis we used the FibroScan® 520 compact model (Echosens, Paris, France) equipped with the M- (normal) or XL- (obese) probe. Firstly, the inspection was performed using an M-

probe with a 3.5 MHz transducer frequency. Then, the XL probe (2.5 MHz) was used if the distance between the skin and the liver capsule was higher than 25 mm. If 10 acquisitions were made with an interquartile interval not exceeding 30%, reliable measurement was determined to have occurred. The cut-offs for liver stiffness measurements (LSM) values were: 5.6 kPa for mild fibrosis (F1), 7.1 kPa for significant fibrosis (F2), 9.5 kPa for advanced fibrosis (F3), and 12.5 kPa for cirrhosis (F4).

Statistical processing was carried out using *Microsoft Excel* and *SPSS version 28* (Inc., Chicago, IL) programs. While categorical variables were expressed as absolute values and percentages, continuous variables with normal distributions were expressed as mean SD. To compare categorical data, the Chi-square test was employed. To compare the arithmetic means of a parameter analyzed in two samples, we used the t-Student test. We employed nonparametric tests, such as the Mann-Whitney U test, and the Kolmogorov-Smirnov test to determine whether the data distributions were normal. A *p*-value of 0.05 was used to determine the statistical significance of the results. When both variables were binary, we also calculated the corresponding OR (Odds Ratio) risks - the measure of the association between the presence of a risk factor and the occurrence of an event; these risks were calculated both in absolute value and as a 95% confidence interval.

The study was carried out in accordance with the ethical principles of the Declaration of Helsinki, the protocol being explained in detail to all patients. Informed consent for participation in the study was obtained from all patients and/or their relatives.

RESULTS

General characteristics of the study population

During the study period, 730 patients with HCV liver cirrhosis were treated with DAAs therapy, of which 35 were diagnosed with non-malignant PVT, corresponding to a total incidence of 4.8%. The mean age of patients with non-malignant PVT was 57.86 ± 7.06, the female gender being prevalent (57.1%), and patients came equally from urban or rural areas (51.4% vs. 48.6%). The mean time from SVR to complication was 290.00 ± 116.639 days, with a minimum of 74 days and a maximum of 450 days. The majority of patients with post-SVR PVT received LED/SOF (71.4%), while the rest received PrOD (28.6%). The study group consisted of 24 patients (68.6%) diagnosed with acute PVT and 11 patients (31.4%) with chronic PVT; most patients diagnosed with acute PVT associated partial occlusion of the portal vein (19 patients - 79.2%) with occlusion at the level of the trunk (15 patients - 62.5%). Half of the patients treated with antivirals were included in the Child C category (45.7%), just under a third were Child B (31.4%), and almost a quarter of patients were in the Child A category (22.9%), with no statistically significant differences between MELD score values. Among patients with PVT post-SVR, 22.9% did not have esophageal varices at the time of inclusion in the treatment, the number of patients with small and large esophageal varices being almost balanced (37.1% in the first case and 40.0% in the second). All patients presented various types of comorbidities: essential hypertension - 35 patients (100%), type 2 diabetes - 24 patients (68.57%), obesity - 12 (34.3%), psychiatric - 6 (17.1%), and neoplastic antecedents - 2 (5.7%) (tab. I).

Evolution of liver function and the degree of liver fibrosis in patients with non-malignant PVT post-SVR during the follow-up

Over the course of the study, an improvement in liver function was observed during antiviral treatment, with improvement of the Child-Pugh score and MELD at the time of SVR (45.7% CP class A, 54.3% CP class B, 100% patients with MELD score < 15). The evolution changes at the 48-week assessment, with a slight increase in the proportion of patients in Child B class (68.6%). At the 3-year assessment/or at the occurrence of the thrombotic event, however, a significant deterioration of liver function was observed compared to the initial situation (62.9% CP class B, 37.1% CP class C; 11.4% MELD <15, 88.6% MELD ≥15) (figs. 1, 2).

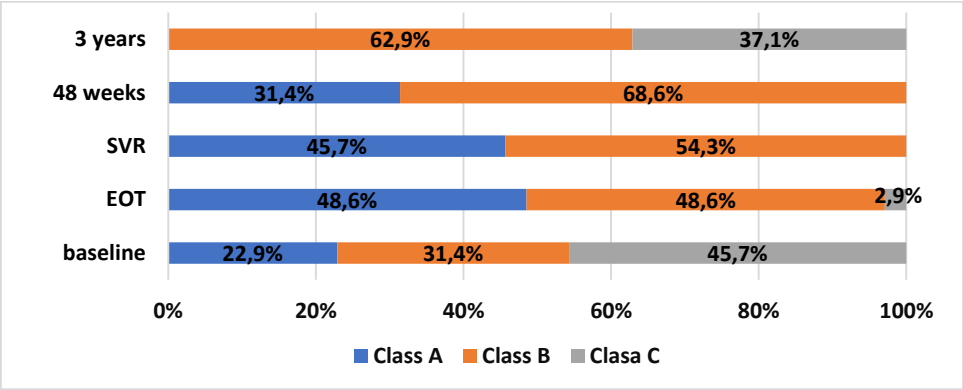

Fig. 1. Evolution of the Child-Pugh score during follow-up in patients with PVT post-SVR

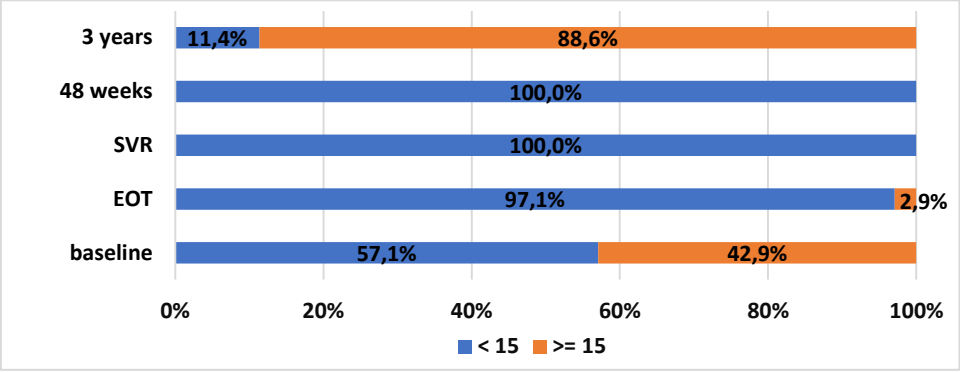

Fig. 2. Evolution of the MELD score during follow-up in patients with PVT post-SVR

Among the patients who achieved SVR with a pre-treatment CPT score ≥ 6 points, 23 (65.71%) showed an improvement in CPT score at the end of treatment (EOT). Among patients whose CPT score decreased ≥ 1 point, the cumulative incidence of non-tumoral PVT was 0%, 2.6%, and 6.5% at 1, 2, and 3 years, respectively, after the end of antiviral therapy, while the rates in those without a decrease in CPT were 8%, 10.8%, and 10.8%. Although the difference did not reach statistical significance (sHR: 0.454 (95% CI: 0.01-2.18; p = 0.331), the incidence of non-tumoral PVT was lower in patients who had an improvement in liver function during treatment, justifying the consideration of liver function pre/post - treatment as risk factors for the development of non-tumoral PVT.

In the case of the variation in the degree of liver fibrosis, a similar process is observed, with a significant decrease in Fibroscan values when evaluating SVR (19.30 kPa from 31.23 kPa to baseline), with the same descending trend at 48 weeks (16.81 kPa) and 3 years (18.21 kPa), but with higher values >12 kPa.

Regardless of whether SVR implies improvement of the liver function, the highest risk of non-tumoral PVT remained in patients with advanced liver disease. Comparative distribution by Child-Pugh classes

of patients with PVT - post SVR: 22.9% patients with Child A, 31.4% patients with Child B, and 45.7% patients with Child C.

Risk factors for non-malignant PVT post-SVR in patients treated with DAA

Among the qualitative parameters evaluated as risk factors for the occurrence of non-malignant PVT in patients with HCV liver cirrhosis treated with antivirals in the studied group, the presence of type II diabetes, ascites, hepatic encephalopathy and the decompensated status of liver disease reached the threshold of statistical significance (tab. II).

The analysis of quantitative parameters compared between patients with non-malignant PVT and the rest of cirrhotic patients treated with antivirals, revealed statistically significantly increased values for PT, INR, aPTT, ASAT, ALAT, BT, MELD score, and statistically significant values low for platelets, AP and albumin in patients with non-malignant PVT post-SVR (tab. III).

DISCUSSION

One of the triumphs of medical therapy in the last two decades, proved by the effectiveness of direct-acting antivirals, is firmly proven by achieving SVR in over 95% of treated patients (12) and which was associated with reducing the progression of chronic hepatitis to cirrhosis, decreasing the risk of decompensation liver and portal hypertension complications, decreasing the need for liver transplantation and decreasing the risk of hepatocellular carcinoma (HCC) (2). Despite effective treatments related to HCV, in addition to the complications and characteristics specific to each progressive stage of liver disease, thromboembolic events could be associated even in patients responding to antiviral treatment.

Non-malignant PVT, an intensely debated topic in recent years, represented the most frequent thromboembolic complica-

tion that might occur in the natural course of liver cirrhosis. The prevalence of PVT varies according to the degree of liver failure and the presence of HCC, being up to 1% in patients with compensated liver cirrhosis, reaching 8% - 25% in liver transplant candidates and 40% in patients with HCC (13). In our study the incidence of non-malignant PVT post-SVR was 4.8%, higher than that reported to date in other studies (4). Stine JG *et al.* reported the experience of seven patients on DAA treatment, followed in a 4-year prospective study, who developed non-malignant PVT (one case with total PVT and six cases with partial PVT) after obtaining SVR (8). During this period 461 subjects were treated with direct antivirals, of which 54.8% (231 patients) were cirrhotic. The incidence of PVT post-SVR was 3% which, although lower than the incidence rates reported in the literature, is not expected given that most patients were not decompensated. At the same time, Russo *et al.* (4) identified 2 cases of non-malignant PVT in a prospective study that included 58 patients treated with antivirals and with SVR, which corresponds to an incidence of 3.44%, lower than that identified in our study. Mandorfer M *et al.* recently reported an incidence of non-malignant PVT of 2.8% in a prospective study of 354 patients with HCV and SVR cirrhosis, much lower than previously reported (5).

The pathogenesis of thrombosis is multifactorial, based on the elements of Virchow's triad: vascular stasis, endothelial injury and hypercoagulability (14, 15, 16). Numerous pieces of evidence stated the fact that the C virus hepatitis could activate hemostasis, and the endothelial damage, the inflammation described at the level of the vascular wall, the changes in the level of the hepatic microcirculation as well as the alteration of the coagulation parameters determined by the HCV infection represent factors that contribute to the occurrence of thrombotic events in advanced liver disease (17).

The majority of patients with non-malignant PVT post-SVR were classified as Child-Pugh B (31.4%) and Child-Pugh C (45.7%), with Child-Pugh A being in the minority (22.9%). Also, most patients with non-malignant PVT post-SVR had a MELD score ≥ 15 at the time of initiation of antiviral treatment. These results obtained in our study were different compared to the data reported in the whole literature. The prospective study by Stine *et al.* (8) included only patients with compensated HCV liver cirrhosis (Child A), which was why the occurrence of PVT post-SVR was an unexpected event, appearing on the background of a perfectly compensated field. In contrast, Russo *et al.* (4) detected non-malignant PVT in 2 patients who were with Child B, a similar situation to the cases reported by Mandorfer B *et al.* (5), where non-malignant PVT post-SVR was found in patients with decompensated liver cirrhosis.

In the studied group, the gender distribution was balanced, with the female gender having a higher weight (57.1%). This distribution of cases is also consistent with the epidemiological data from the specialized literature published for Romania, which reports a higher prevalence of HCV infection in the female sex (18), a fact that justified the larger number of women who addressed for evaluation to initiate antiviral treatment. The mean age of patients with nonmalignant PVT treated with antivirals was 57.86 ± 7.068, similar to the age of patients who experienced thrombotic events reported in other studies (4, 5, 8).

The mean time from SVR to complication was 290.00 ± 116.639 days, with a

minimum of 74 days and a maximum of 450 days. Time to PVT was similar to Stine *et al.* (8) at 272 ± 204 days, with 5 patients diagnosed with PVT < 365 days after obtaining SVR. Mandorfer *et al.* (5) showed that non-tumoral PVT in responders was detected during a mean follow-up of 37.1 months, whereas 8 (4.5%) of patients without SVR were diagnosed with malignant PVT during a mean follow-up of 42.2 months. The shortest period was reported by Russo *et al.* (4), the occurrence of the thrombotic event being at the time of SVR12. A unique case was reported by Garg H *et al.* (19) who described 2 clinical cases with acute nonmalignant PVT discovered during antiviral treatment in 2 patients who received treatment with sofosbuvir and ribavirin. The mechanism underlying these events was interpreted as a simple drug reaction, these antivirals exhibiting idiosyncratic (type B) drug reactions, but they are rare and unpredictable.

Various studies on the efficacy of DAA treatment have shown that achieving SVR in patients with viral hepatitis C cirrhosis was associated with improved MELD and Child-Pugh scores, which reflect improved liver synthesis function (20, 21, 22, 23), a hypothesis that was also confirmed in our study. At the initial assessment, of the 35 patients with PVT post-SVR, almost half (45.75%) were in Child C, one third were in Child B (31.4%), and the remaining 22.9% were part of the Child A. The situation improved along the way, so that at the end of the treatment only one patient (2.9%) remained classified in the Child C, the others being classified in equal percentages in the Child A classes and B, evolution that remained favorable also at SVR12. The results obtained in our study are also confirmed by Gentile *et al.* (24) in an Italian multicenter prospective study of 89 patients with decompensated HCV and responders to antiviral treatment, in whom the rate of change to Child A was 62% 24 weeks after obtaining SVR.

In the present study, the process was also similar to the evolution of the MELD score: at the initial assessment, the proportions of patients with a MELD score below the threshold value of 15 and above it were relatively balanced, with a slight superiority for patients with a MELD score < 15 (57, 1%). At the EOT, the situation improved significantly, only one patient (2.9%) remained with the MELD score > 15, a situation that remained favorable at the time of SVR12. In the SOLAR-1 and SOLAR-2 studies, patients with genotype 1 or 4 decompensated HCV cirrhosis who received DAA showed improvement in both MELD and Child-Pugh (25, 26). Similar results were also reported by Poordad F *et al.* (27) in the ALLY-1 study, where all patients with decompensated cirrhosis and SVR, regardless of genotype, showed improvement in liver function. On the other hand, Marco and Calvaruso showed that in patients with decompensated cirrhosis (ascites, hepatic encephalopathy, bleeding from variceal rupture) treated with antivirals, obtaining SVR does not improve liver dysfunction or mortality (28).

Similarly, in the case of the variation in the degree of liver fibrosis, a similar process was observed, with a significant decrease in Fibroscan values at the SVR assessment, with the same downward trend at 48 weeks and 3 years, but with higher values >12 kPa. These results attest to the fact that there is a risk of thrombotic complications in the portal system even after achieving SVR, the persistence of portal hypertension favoring intravascular blood stasis being considered a key element in the occurrence of portal vein thrombosis (29, 30,

31, 32, 33, 34).

Regardless of whether SVR implies improvement of the liver function, the highest risk of non-tumoral PVT remained for patients with advanced liver disease (Child C). The results of our study are confirmed by Mandorfer *et al.* who observed that an elevated Child-Pugh score was the only independent risk factor for the development of non-malignant PVT post-SVR, with patients with a Child A score having the lowest risk (5).

Among the qualitative parameters evaluated as risk factors for the occurrence of non-malignant PVT in patients with HCV liver cirrhosis treated with antivirals, the presence of type II diabetes, ascites, hepatic encephalopathy and the decompensated status of liver disease reached the threshold of statistical significance. Quantitative parameters correlated as risk factors with non-malignant PVT in the studied group were increased BT and MELD score values, low albumin values, but also the persistence of an increased degree of post-SVR liver fibrosis. Age over 65 years, male gender, obesity and NSBB treatment were not risk factors in the study group. Stine *et al.* mentioned that patients with HCV cirrhosis treated with antivirals have a high risk of developing non-malignant PVT post-SVR, in the context where the 7 patients who developed a thrombotic complication were with Child A (8). This risk is independent of the value prothrombin time, INR or platelet count, the risk of PVT being due rather as a reaction to an overcorrection of an already fragile coagulation balance in the cirrhotic patient.

CONCLUSIONS

Achieving SVR decreases the risk of decompensation among cirrhotic patients, but the risk for thrombotic events still remains. The severity of the liver damage is a risk factor for the occurrence of nonmalignant PVT post-SVR, the majority of patients who developed this complication being Child-Pugh C score. The persistence of liver fibrosis with higher values >12 kPa after obtaining SVR demonstrates the persistence of portal hypertension and implicitly, an increased risk for the occurrence of nonmalignant PVT, which is why these patients must continue to be carefully monitored according to the protocol. Future research should focus on personalizing post-SVR care based on individual risk of complications.

FACTOR XIII V34L POLYMORPHISM IN A POPULATION OF PATIENTS WITH FAMILIAL HYPERCHOLESTEROLEMIA FROM NORTH-EASTERN ROMANIA (Abstract): Familial hypercholesterolemia (FH) is one of the most frequent inherited genetic disorders of the cholesterol metabolism that has an autosomal dominant or multifactorial inheritance. Factor XIII is also called the factor that stabilizes the fibrin, being an enzyme that makes the bond between the fibrin molecules during the clot formation. The gene for factor XIII is localized on 6p24-25 and can suffer a substitution in 103G>T position (V34L polymorphism), that can decrease the stability of the clot, offering protection for thromboembolic events and a decreased risk for myocardial infarction and coronary artery disease. **Materials and methods:** A cross-sectional study was conducted in the Cardiovascular Rehabilitation Clinic from the Clinical Rehabilitation Hospital from Iasi from 1st December 2020 to 31st of March 2022, included 70 patients diagnosed with certain FH based on the Dutch Lipid Clinical Network score (DLCN) and 20 patients in the control group. **Results:** The homozygous patients had the highest values of the corrected LDL-C and the heterozygous patients had the lowest total bilirubin concentrations. The patients included in the control group that had the homozygous variant had the lowest total cholesterol and non-HDL concentrations. **Conclusions:** This approach enables the implementation of targeted management and treatment approaches to effectively mitigate the risks associated with this condition. The costs of genetic testing decrease over time, the significance of this information is likely to increase even further. **Keywords:** FAMILIAL HYPERCHOLESTEROLEMIA, FACTOR XIII V34L POLYMORPHISM, LIPID PROFILE.

World Health Organization attributes 17.9 million deaths each year to cardiovascular diseases, being thus the leading cause of death worldwide (1). Atherosclerosis is clinically manifested by pectoral angina, stroke, coronary syndrome, peripheral ar-

tery disease, being the central element in the development of cardiovascular pathologies (2).

Familial hypercholesterolemia (FH) is one of the most frequent inherited genetic disorders of the cholesterol metabolism that has an autosomal dominant or multifactorial inheritance (3). Patients might have either a homozygous or a heterozygous genotype, this influencing the severity of the disorder and the age of the cardiovascular disease manifestations (4). Mutations in the LDL-R, APOB, and PCSK9 genes cause the development of the autosomal dominant form. Because of lifelong exposure to very high levels of low-density lipoprotein cholesterol (LDL-C), the patients with FH are often diagnosed after a major cardiovascular event (5, 6).

Primary prevention is extremely important in these patients, due to the fact that more than 90% of the patients with FH from the United States of America have been diagnosed only after a major cardiovascular event (7).

Factor XIII is also called the factor that stabilizes the fibrin, being an enzyme that makes the bond between the fibrin molecules during the clot formation (8). Studies demonstrate that a mutation found in the gene for factor XIII is considered as a protective factor for cardiovascular events. The enzyme is formed from two subunits A and two subunits B (that transport the subunits A in the plasma), factor XIII being activated through the rupture of the N-terminal end of the units A by thrombin and dimer dissociation from the B subunits in the presence of calcium (9). The activated factor XIII makes a bond between the fibrin chains α and γ and between α2-antiplasmin and fibrin, conferring mechanical and proteolytical resistance to the clot. The gene for factor XIII is localized on 6p24-25 and can suffer a substitution in 103G>T position (V34L polymorphism), that can decrease the stability of the clot, offering protection for thrombo-embolic events and a decreased risk for myocardial infarction and coronary artery disease (10, 11). The polymorphism increases the thrombin activation and changes the structure of the fibrine, effect that is correlated with the blood fibrinogen concentration. This mechanism is worth describing it, as in patients with normal fibrinogen concentrations, the polymorphism creates clots in with thinner fibers and less permeability, but it forms thrombi with larger fibers and higher permeability and susceptibility to fibrinolysis in patients with high concentrations of fibrinogen. Because abnormal fiber thickness and altered clot permeability and stability are associated with increased thrombosis risk, these findings suggest that in population studies, both FXIII genotype and plasma fibrinogen concentration should be considered when calculating thrombosis risk (12).

MATERIALS AND METHODS

We performed a cross-sectional study that was conducted in the Cardiovascular Rehabilitation Clinic from the Clinical Rehabilitation Hospital Iasi between 1st December 2020 to 31st of March 2022. We included 70 patients diagnosed with certain FH based on the Dutch Lipid Clinical Network score (DLCN). The inclusion criteria consisted of patients with a DLCN score more than 8 points that signed the informed consent. We excluded all the patients that had secondary causes of hypercholesterolemia, such as patients diagnosed with severe chronic kidney disease or nephrotic syndrome, severe liver disease, hypothyroidism, uncontrolled diabetes mellitus (DM) or patients with a fatty diet. The

group of patients with HF were compared with a control group that included 20 patients with normal lipid profile.

One of the criteria used in the DLCN score is the LDL-C concentration. In our study, we adjusted the value for the patients that had already in the last six months in their medical treatment statins or ezetimibe. Haralambos *et al.* described this correction factor, based on a review that included 71 original articles collected before the establishment of the familial hypercholesterolemia criteria (13).

The anamnesis and physical examination were conducted by a single researcher, that included the patients' medical history, the blood pressure and heart rate, along with the patients' drug history (including lipid lowering therapy). Also, the investigator recorded the blood tests, such as liver function tests, creatinine, calcium, alkaline phosphatase and lipid profile (total cholesterol, LDL, HDL, non-HDL, triglycerides).

DNA was prepared from peripheral blood cells using PureLink® Genomic DNA Kit (Thermo Fisher Scientific). We assessed relevant mutations in FXIII V34L by reverse hybridization using CVD StripAssay kit (ViennaLab Diagnostics, Vienna, Austria).

After the amplification by the polymerase chain reaction (PCR) with biotinylated primers, the PCR products were directly hybridized on the StripAssay® test strips, that contain allele-specific oligonucleotide probes immobilized as parallel lines. Afterwards, the mutant and/or wild type alleles were visualized through an enzymatic color reaction that was visible on the strip.

Positively strained lines were analyzed through the online tool StripAssay® Online Calculator (ViennaLab Diagnostics) and for the gene was analyzed the underlying genotypes.

All the patients signed the informed consent that were included in the study and the ethics committee approval was obtained from both "Grigore T. Popa" University of Medicine and Pharmacy Iasi (certificate of approval dated 15th June 2020) and Clinical Rehabilitation Hospital from Iasi (certificate of approval dated 25th November 2020).

The data analysis was realized using *SPSS 20.0* (Statistical Package for the Social Sciences, Chicago, Illinois). When evaluating the continuous variables, the data were presented as mean ± standard deviation or as a median with interquartile range. When evaluating the categorical variables, the data were presented as the number of cases with percent frequency. We evaluated also the distribution of the variables. When we compared continuous normally distributed variables, we used the Independent Samples t-Test in case of two samples and in case of comparisons of more than two samples we used One-Way ANOVA test. When categorical comparisons were made, we used Chi-square test or Fisher's exact test. In the situations where the distribution of the continuous variables did not satisfy the assumption of normality, the Mann-Whitney U test was performed. When we evaluated the correlations between continuous variables, Spearman correlation coefficient was calculated. A statistical significance was considered at a two-sided p-value less than 0.05.

RESULTS

For our research, we enrolled 70 patients diagnosed clinically with familial hyper-cholesterolemia that were compared with 20 healthy controls. The mean age of the patients diagnosed with FH was significantly higher, but both groups included mostly middle-aged adults. The living environment of both groups was mostly urban.

There were no statistically significant differences regarding the alcohol consumption or the smoking status, but it is worth mentioning that none of the patients from the control group did not smoke more than 10 packs year. Regarding the comorbidities, the patients with FH had significantly more associated diseases compared to the control group. All the above can be observed in first table.

TABLE I.
General characteristics of the studied groups

General characteristics	HF group (n = 70)	Control group (n = 20)	p
Gender n (%)			
Male	29 (41.4%)	7 (35.0%)	0.796
Female	41 (58.6%)	13 (65.0%)	
Living environment. n (%)			
Rural	18 (25.7%)	6 (30.0%)	0.776
Urban	52 (74.3%)	14 (70.0%)	
Age. years (mean ± SD)	54.65 ± 12.81	41.70 ± 13.51	<0.001
BMI. kg/m^2 (mean ± SD)	28.75 ± 4.96	24.95 ± 6.19	0.005
Alcohol consumption	35 (50%)	8 (40%)	0.459
Hypertension	48 (68.6%)	3 (15%)	< 0.001
Myocardial infarction	7 (10%)	3 (15%)	0.686
Chronic ischemic heart disease	12 (17.1%)	0 (0%)	absent
Atherosclerotic cardiovascular disease	36 (51.4%)	3 (15%)	0.004
Basal hyperglycemia	29 (41.4%)	4 (20%)	0.114
Creatinine, mg/dL	0.99 (0.90;1.09)	0.94 (0.88;1.02)	0.246
Ca, mg/dL	9.23 (8.96;9.45)	9.00 (8.75;9.38)	0.020
TGO, UI/L	19.85 (15.92;27.90)	17.35 (13.75;21.55)	0.113
TGP, UI/L	20,20 (16,02;32,95)	17,50 (15.77;27,92)	0,455
Bilirubin, mg/dL	0,53 (0,43;0,70)	0,53 (0,44;0,69)	0,988
Total cholesterol, mg/dL	278,00 (249,50;310,25)	201,00 (173,80;223.75)	0,000
HDL cholesterol, mg/dL	57,82 ± 16,52	46,56 ± 10,24	0,000
Non-HDL cholesterol, mg/dL	221,25 (186,45;253,42)	160,55 (132,30;176,60)	0,000
LDL cholesterol, mg/dL	196,02 ± 47,02	126,17 ± 40,40	0,000
LDL cholesterol corrected, mg/dL	296,29 (224,84;389,75)	130,75 (97,10;155,87)	0,000
Triglycerides, mg/dL	164.70 (104.82;227.57)	100.30 (93.47;144.60)	0.007

The studied polymorphism in the two groups was FXIII V34L. In the group of patients with FH, the cardiovascular and metabolic diseases were observed especially in the ones that had the wild type genotype. When evaluating their biological profile, we observed that they had the highest values of the corrected LDL-C in the homozygous patients, a statistically significant differentiation between them and the patients that had wild type or homozygous genotypes. Moreover, the heterozygous patients had the lowest total bilirubin concentrations, being observed statistical significance between them and the homozygous ones (tab. II).

TABLE II.

Correlations between the polymorphism of Factor XIII V34L and clinical and paraclinical parameters

	Wild Type	Heterozygous	Homozygous	p_1	p_2	p_3
FXIII V34L						
Hypertension	28 (66.7%)	20 (76.9%)	0 (0%)	0.422	absent	absent

P1 – statistical significance between wild type and heterozygous; p2 – statistical significance between wild type and homozygous; p3 – statistical significance between heterozygous and homozygous.

The patients included in the control group that had the homozygous variant had the lowest total cholesterol and non-HDL concentrations. existing statistically significant differences between these parameters and those of the wild type patients. Another aspect that can be observed in Table III is the fact that the patients diagnosed with FH had lower heart rates and higher liver function tests (TGO. TGP) compared to the ones from the control group on each genetic genotype.

DISCUSSION

In our study, we observed that all homozygous patients with FH were diagnosed with basal hyperglycemia, existing a significant difference between them and the heterozygous ones, results that were not observed in the subjects included in the control group. Phasha *et al.* studied the factor XIII V34L polymorphism in diabetic patients in a South American population. The authors observed that the V34L allele was more frequent in the group of patients without diabetes compared to those diagnosed with this pathology. Thus, they describe that no significant correlations were observed between polymorphism and disease (14). Further studies on this topic will be necessary, which will include a larger number of patients with FH, to establish a definite correlation between the two.

Evaluating the lipid profile of the two groups, we observe that the homozygotes with FH have the highest total cholesterol, LDL, corrected LDL, and non-HDL, while in the control group they had the lowest serum concentrations when compared to the wild type or the heterozygotes. Researchers have shown in a recent study that an increase in factor XIII activity is associated with a higher risk of developing myocardial infarction in young patients, but this activity does not correlate with the V34L variant. They also evaluated several haplotypes of the factor XIII gene and demonstrated that there were no significant differences between the associated polymorphisms and the lipid profile of the patients (15).

The results described by Ambroziak *et al.* are consistent with those of the control group, but not with those of the FH patient group. This fact may be due to the increased serum concentrations of their lipid profile, homozygous patients diagnosed with FH requiring more careful monitoring, but this observation will have to be confirmed later by studies involving a larger group of patients.

The present study is a princeps one, the first in our country, to our knowledge. The results obtained so far are to be completed by integrating a larger number of patients, in a multicenter study.

CONCLUSIONS

Familial hypercholesterolemia is frequently undertreated, resulting in a lack of progress in meeting treatment objectives and an elevated risk of coronary heart disease (CHD). It also serves as an exemplary case for precision medicine, as it seeks to identify through genetic diagnosis a specific subset of individuals who are at high risk of experiencing significant illness and mortality. This approach enables the implementation of targeted management and treatment approaches to effectively mitigate the risks associated with this condition.

National databases and special registries would serve as valuable tools for clinical research and enhancing healthcare planning and patient care. Furthermore, as the cost of genetic testing decreases over time, the significance of this information is likely to increase even further.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

CHRONIC HEPATITIS B INFECTION IN PEDIATRIC POPULATION: A RETROSPECTIVE STUDY FROM A TERTIARY CENTER IN NORTH-EASTERN ROMANIA (Abstract): Chronic viral hepatitis B is the precursor stage of cirrhosis and the 10th leading cause of death worldwide. WHO estimated in 2019 that approximately 296 million people were chronically infected with the hepatitis B virus and over 800,000 deaths. **The aim of study** was to describe characteristics of chronic HBV infection in pediatric population from a tertiary center in North-Eastern Romania. **Materials and Methods**: A retrospective study was conducted on 148 pediatric patients with chronic HBV infection who had visits from 2011 to 2019 to St. Mary's Hospital Iasi (Romania). The HVB infection in study group was analyzed regarding demographic characteristics, distribution of pediatric patients in relation to vaccination status, risk factors, HBV infection stage, and clinical manifestations. The qualitative variables were characterized through frequencies distributions. The quantitative variables were characterized through descriptive statistics (averages, standard deviations). $P < 0.05$ was the threshold for significance. **Results**: Most of the patients (87,83%) had vertical transmission, while 18.91% had horizontal transmission. Most of the pediatric population was vaccinated (87.83%), while 11.48% had incomplete vaccination. The most common risk factor was vertical transmission (81.8%), followed by horizontal transmission, surgical interventions (10.13%), frequent hospitalizations (4.1%), and dental procedures (3.4%). Among patients with HBV infection, most of them presented loss of appetite (16.2%), followed by abdominal pain (12.8%), hepatomegaly (12.2%), and physical asthenia (4.1%). **Conclusions**: Most children from our study were in chronic hepatitis B phase and immune-tolerant phase. Pediatric patients with chronic viral B infection can experience a slow progression of the disease without specific signs and symptoms for a long period, especially when the diagnosis is made at an infant or young child age. **Keywords**: CHILDREN, HEPATITIS B VIRUS, VACCINATION, TRANSMISSION.

Hepatitis B represents a significant health challenge worldwide, characterized by high rates of morbidity and death. Annually, 1.5 million new cases of HBV infection emerge, despite the effectiveness of vaccination and the potential to curb viral replication and spread through medication (1). It is estimated that the global preva-

lence of HBV infection in children up to 5 years of age is 1.3%, significantly lower compared to the 1980-2000 period (4.7%) (2). However, despite increased access to immunization, about 2 million new HBV infections are recorded each year in the 0-5 years age group (3). Given that the majority of HBV infections occur through vertical transmission from mother to child during pregnancy or childbirth, there is an increased risk (over 90%) of chronic HBV infection (over 6 months). HBV infection can progress to hepatic fibrosis, cirrhosis, and hepatocellular carcinoma, although pediatric patients are rarely diagnosed with these conditions (4). However, approximately 3-5% of children with chronic HBV infection develop cirrhosis, while 0.01-0.03% develop hepatocellular carcinoma (5). In the initial stage of HBV infection, typically contracted at birth, the virus shows high replication levels. This is characterized by the presence of HBeAg and extremely high HBV DNA concentrations in the blood, often exceeding 100 million or even 1 billion IU/mL. This stage, known as the HBV infection HBeAg positive (immune-tolerance phase), usually persists for a period ranging from 10 to 30 years. During this time, the likelihood of naturally eliminating HBeAg from the body is quite low. Statistically, after two decades of being infected, the cumulative probability of spontaneously losing HBeAg is about 2% in the first three years, increasing to only 15% after 20 years (6). The second phase of HBV infection, hepatitis B HBeAg positive (often referred to as the immune-clearance or immune-active phase), typically emerges in the third or fourth decade of the disease in individuals who contracted HBV early in life. This phase is marked by the continued presence of serum HBeAg, a gradual reduction in HBV DNA levels, and either increased or variable ALT levels, indicative of HBeAg positive chronic hepatitis. Some patients may undergo multiple exacerbations characterized by temporary loss of HBeAg and periodic elimination of HBV DNA from the blood. In such cases, the recurring episodes of hepatitis increase the likelihood of developing cirrhosis and hepatocellular carcinoma. HBeAg negative hepatitis is identified by the absence of HBeAg in the serum, often accompanied by the presence of anti-HBe antibodies. This condition also features ongoing or variable serum HBV DNA levels that are generally lower than those found in HBeAg positive patients, along with fluctuating or consistently high ALT levels (7). HBeAg negative hepatitis is identified by the absence of HBeAg in the serum, often accompanied by the presence of anti-HBe antibodies. This condition also features ongoing or variable serum HBV DNA levels that are generally lower than those found in HBeAg positive patients, along with fluctuating or consistently high ALT levels (7). HBeAg negative chronic HBV infection, also known as inactive hepatitis phase, is characterized by the presence of antibodies against HBeAg, HBV DNA levels that are undetectable or low (below 2000 IU/mL), and normal ALT levels as defined by standard cutoff values (the upper limit of normal [ULN] is approximately 40 IU/L). Despite having normal serum ALT levels, patients with HBeAg negative chronic infection may still experience histologic inflammation and/or fibrosis (8).

AIM of study was to describe characteristics of chronic HBV infection in pediatric population from a tertiary center in North-Eastern Romania.

MATERIALS AND METHODS

A retrospective study was conducted on 148 pediatric patients with chronic HBV

infection, with at least one medical visit to St. Mary's Hospital Iasi (Romania), from January 1, 2011 to December 31, 2019.

Chronic HBV infection was defined as the presence of hepatitis B surface antigen (HBsAg) for at least 6 months.

The inclusion criteria were:

- age from 0 to 18 years at their initial pediatric visits with the diagnosis of chronic HBV infection;

-the presence of hepatitis B surface antigen (HBsAg) for at least 6 months.

Each patient's demographic characteristics, clinical history, family history of immediate family members, prior HBV vaccination, and laboratory values were extracted from patient charts. Characteristics of HBV vertical transmission were as follows: mother' age and occupation, comorbidities, maternal HBeAg status, type of delivery. Patient charts were reviewed for HBV vaccination and receipt of hepatitis B immunoglobulin (HBIG). The phases of chronic HBV infection were analyzed cross-sectionally according to the following laboratory values: HBeAg status, anti-HBe status, ALT, and HBV DNA levels. The characteristic was based on the American Association for the Study of Liver Diseases (AASLD) hepatitis B guidance 2018 (9). The HVB infection in study group was analyzed regarding demographic characteristics, distribution of pediatric patients in relation to vaccination status, risk factors, HVB infection stage, and clinical manifestations

Statistical analysis. The statistical analyses were performed in SPSS 29.0. The qualitative variables were characterized through frequencies distributions. The quantitative variables were characterized through descriptive statistics (averages, standard deviations). $P < 0.05$ was the threshold for significance.

RESULTS

Table I exposes demographic characteristics of the study population. On age groups, the distribution was as follows: 0-1 yrs. (20.27%), 2-5 yrs. (25.35%), 6-10 yrs. (22.97%), 11-14 yrs. (18.91%), 15-18 yrs. (11.48%). Regarding gender, 52.02% were boys and 47.97% were girls. Regarding the birth type, 80,4% were born naturally and 19.59% were born through C-section with overall median weight at birth 3,200 g. Most of the patients (81.08%) had vertical transmission, while 18.91% had horizontal transmission. Most of the pediatric population was vaccinated (87.83%), while 11,48% had incomplete vaccination. Most of the patients (72.29%) were breastfed, while 27.7% were bottle-fed. Patients from low socioeconomic families (rural provenience) (61.48%) predominated over patients from urban families (38.51%).

Distribution of pediatric patients in relation to vaccination status and birth weight is exposed in figure 1 (93.2% were children with $\geq$ 2,500 g, 4.7% were between 1,500-2,500 g, and 2.0% were < 1,500g) (fig. 1).

According to the study data, 3 children weighed < 2,000 g and 7 children between 1500 and 2,000 g. Among those with LBW (Low Birth Weight), only one was born to a mother with HBV infection, and 2 of them did not have a complete vaccination schedule, meaning they were either not vaccinated by the time of discharge from the maternity hospital or at the age of one month. For those born weighing less than 2,500 g, all were vaccinated. The viral status of the mothers at the time of birth is unknown (tab. II).

The distribution of patients from HBsAg positive mothers. The frequency of administering hepatitis B immunoglobulin to children from HBsAg positive mothers is presented in Fig. 2 (3.4% - received hepatitis B immunoglobulin; 35.1% - did not

receive; 61.5% - unspecified).

The distribution of patients according to risk factors is presented in Table II. It is noted that the most common risk factor is vertical transmission (81.8%), followed by horizontal transmission, surgical interventions (10.13%), frequent hospitalizations (4.1%), and dental procedures (3.4%).

Vertical transmission	121	81,8
Horizontal transmission	27	18,2
Blood transfusions	1	,7
Total	148	100,0

Among the patients, all phases of HBV infection were detected, with the majority (49.3%) being diagnosed in the phase of chronic viral hepatitis B Ag HBe +, followed by HBV infection Ag HBe + in 27.7% of children. Generally, the second phase, that of immunotolerance, predominates in the pediatric age, but in our group, the majority had hepatocytolysis syndrome over x2 VN (normal value) (fig. 3).

Out of a total of 148 children, 19.6% presented with anti-HBe antibodies at the time of diagnosis. Spontaneous seroconversion was predominantly recorded in those with chronic HBeAg- infection (73.9%), and 81.8% of those with chronic HBeAg- hepatitis were positive for anti-HBe antibodies. It is known that seroconversion in the HBe system is more common in the pediatric population than in adults (tab. IV).

The clinical manifestations recorded in the pediatric population with HBV infection are presented in Table V. Among patients with HBV infection, most of them presented loss of appetite (16.2%), followed by abdominal pain (12.8%), hepatomegaly (12.2%), and physical asthenia (4.1%). Other nonspecific signs were rec-

orded such as arthralgia (2%), headache (2%), dysphagia (1.4%), or weight stagnation (1.4%). Other possible clinical manifestations were also sub febrility, sleep disturbances, or scleral and skin sub icterus.

DISCUSSION

Although there are many studies that have investigated the risk factors for HBV infection in infants, data from Romania is very scarce and an urgent update is requested. In our country, the major route of HBV infection in children is the vertical transmission which despite universal immune prophylaxis, remains evident and is associated with maternal HBV DNA levels (10). Most children from our study were in chronic hepatitis B phase and immune-tolerant phase, 37.8% were without clinical manifestations, while 36.48% did not have liver enzymes increased.

The immunization schedule is dependent on the birth weight and the infectious status of the mother. All newborns weighing 2,000 grams or more from HBsAg-negative mothers are given the vaccine within the first 24 hours, while those weighing less than 2,000 grams can be vaccinated upon discharge or at the age of one month. If the mothers are HBsAg positive at birth, then the vaccine and HBIG are administered within the first 12 hours, regardless of the newborn's birth weight. If the immunological status of the mother is unknown, the vaccine is administered within the first 12 hours after birth to all newborns (11, 12). The fact that 11.48% patients were incomplete vaccinated and 1 didn't get any vaccines shows that there is a lack in family education regarding the immunization scheme especially since most of them (64.70%) are from urban area. Regarding the HBIG administration, unfortunately is not available in maternities and all the mothers must buy it at a quite high price, even if is indicated to all newborns to HBsAg positive mothers. So, a priority in providing immunoglobulin to children from positive mothers by the government is mandatory. Another aspect is the temporary absence of anti-hepatitis B vaccine in ma-

ternities, and some parents forget or delay the time of vaccination. Until 6 weeks of life is used only the monovalent vaccine. After this age is used the polyvalent vaccine in three doses, first at 6 weeks, the next two at 1 month between them. Also, vaccination is safe and indicated in pregnant women or other high-risk groups (13). Besides that, the evaluation of infants should be done at 9-15 months of life, to be sure that they developed an immune response. Usually those who didn't get antibodies are with low weight birth or other risk factors as chronic diseases, genetic factors, HIV coinfection.

It is already known that the most effective way to prevent vertical transmission of the hepatitis B virus is through the administration of the vaccine and hepatitis B immunoglobulin at birth, reducing the risk from 5-25% to 0.7-1.1% (14). However, the risk is particularly present if the mother was not monitored during pregnancy and did not receive the necessary treatment. In our group, only 5 patients received HBIG in the first hours after birth (5.4%), 52 did not receive it (35.1%), while for the remaining 61.5%, relatives stated they were unaware of this immunization or whether the newborn was immunized (15). The low percentage of HBIG administration indicates a lack of information among pregnant women, a deficient interdisciplinary relationship between the family doctor, obstetrician, neonatologist, and gastroenterologist, and the absence of a national program to ensure the availability of immunoglobulin in maternity wards. We observed a downward trend in those with chronic hepatitis Ag HBe+ in relation to age, with the most diagnoses being in infants and young children, then after the age of 2 years, the number of diagnosed cases gradually decreases until 18 years of age.

We found that most of risk factors, besides vertical transmission, are represented by surgical interventions. It is known that until now, the main mode of hepatitis B virus transmission was through infected blood via inadequately sterilized medical instruments (injections, manicure, cosmetic procedures, tattoos, intravenous drugs, piercing), but today there are disposable needles, blood screening for transfusion, and accessible protective equipment (16). In 3 of the patients, we noted familial transmission, knowing the father's positive history and the mother's negative for HBV infection. This can occur either using personal items (razor blades, toothbrushes, scissors, tweezers, sewing needles, glucose meters) or through close interpersonal contact (scratches, domestic accidents with cuts). Therefore, it is requested education of all family members about periodic HBV testing to identify and promptly treat any new cases, education on hygiene and preventive measures to reduce the risk of transmission and avoiding direct contact with the blood or open wounds of infected individuals without adequate protection measures.

It is known that most children are asymptomatic (17). Indeed, in our study, among those with HBeAg+ infection, 56.1% did not show specific signs and symptoms, the results are roughly the same for those with HBeAg- infection, and among those with chronic HBeAg+ hepatitis, 75.3% presented clinical symptoms and signs such as diffuse abdominal pain, in the right hypochondrium or epigastrium, nausea, vomiting, loss of appetite, and physical asthenia.

CONCLUSIONS

Most children from our study were in chronic hepatitis B HBeAg+ phase and chronic HBeAg+ infection phase (immunotolerant). Pediatric patients with chronic viral B infection can experience a slow

progression of the disease without specific signs and symptoms for a long period, especially when the diagnosis is made at an infant or young child age.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

CHALLENGES IN IMMEDIATE AND LONG-TERM POSTOPERATIVE MANAGEMENT IN PATIENTS WITH CORNEAL TRANSPLANT (Abstract): Corneal transplantation is a procedure involving the partial or total replacement of a damaged cornea with a healthy one, serving multiple purposes such as improving visual acuity, for aesthetic reasons, and for tectonic support. The most common procedure used in our clinic is penetrating keratoplasty, which can be burdened with a series of intraoperative and postoperative complications**. The aim:** In this article, we will present our clinic's experience with patients who have undergone and been diagnosed with corneal pathologies through penetrating keratoplasty technique, and the medium and long-term therapeutic difficulties encountered by these patients from 2020 to 2024, at the Ophthalmology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital Iasi. **Materials and methods**: Patients with a history of chemical burns to the cornea, herpetic infection, keratoglobus associated with lagophthalmos, chronic smokers, and those with advanced pseudoexfoliative glaucoma in one eye are included. **Results:** Among the postoperative complications, infections and rejection reactions can occur between 2 weeks and 8 months and are quite challenging to manage. Postoperative infections can be present due to non-conforming sutures, prolonged use of contact lenses, and systemic immunosuppression. Rejection reactions can occur as early as two weeks, with corneal vascularization in the host cornea increasing the risk of graft rejection. Early identification and prompt treatment of inflammation and early infection are facilitating factors in preventing graft rejection. **Conclusions:** Although, in terms of survival, corneal transplantation is the most successful transplant performed in humans, rejection is still the main cause responsible for graft failure. Keratoplasty involves a lengthy healing process; preoperative evaluation and dialogue with the patient are essential to understand the benefits, possible complications, and the need for prolonged treatment. **Keywords:** IMMEDIATE, LONG-TERM, POSTOPERATIVE MANAGEMENT, CORNEAL TRANSPLANT.

INTRODUCTION

Corneal pathologies represent a significant cause of blindness. Visual impairment is due to corneal opacification, keratoconus, Fuchs' endothelial dystrophy, corneal hydrops, marginal degeneration, sphe-

roidal degeneration, pseudophakic bullous keratopathy, other corneal dystrophies, and the failure of a previous graft. Once corneal clarity is lost, transplantation is the current therapeutic procedure with the aim of improving visual acuity (1, 2, 3, 4, 5). Corneal transplantation or keratoplasty is the most common and successful surgery performed worldwide to address a range of corneal pathologies. The first successful corneal allograft was performed by an Irish ophthalmic surgeon, Dr. Samuel Bigger, in 1835 and reported in the Dublin Journal of Medical Science in 1837. He described performing a corneal transplant on a blinded gazelle he encountered while held captive by a nomadic tribe on the outskirts of Cairo (3). However, the world's first human corneal transplant was performed in 1905 by an Austrian surgeon, Eduard Konrad Zirm, marking a significant milestone by performing the world's first full-thickness solid organ transplant (1, 3, 4, 5).

Relative to the number of transplants performed, in the UK, 4,504 corneal transplants were conducted in 2019, while in the USA, there were 85,601 corneas transplanted in the same year. The existence of corneal banks has facilitated such a large number. The USA, Sri Lanka, and Italy are among the few countries with a surplus of tissue donors for export, representing 85%, 9%, and 3% respectively of the total number of exported tissues. Despite the existence of these banks and tissue-exporting countries, at least 55.3% of the world's population does not have access to corneal transplant material (5,8). Corneal transplant procedures are generally classified as penetrating keratoplasty involving the complete removal of the cornea and partial lamellar corneal surgeries, which include anterior lamellar keratoplasty [superficial anterior lamellar keratoplasty (SALK), automated lamellar therapeutic keratoplasty (ALTK), and deep anterior lamellar keratoplasty (DALK)]. Endothelial keratoplasty [Descemet stripping automated endothelial keratoplasty (DSAEK) and Descemet membrane endothelial keratoplasty (DMEK)] broadly fall under this classification (4, 5, 6, 7, 8).

Corneal structure

The cornea is avascular and represents the 1/6 anterior of the outer layer of the eyeball, representing the eye's most important diopter. It is made of six different anatomical layers. The first layer is the epithelium, which consists of squamous cells. The second layer is Bowman's membrane, which has regenerative properties. Most of the cornea, the stroma, contains keratocytes and collagen lamellae that are densely distributed in the anterior part compared to the posterior stroma. Descemet's membrane provides a base for the endothelial cells, which play a key role in maintaining corneal transparency (1, 5, 9). The density of corneal endothelial cells (ECD) decreases progressively throughout life at an average rate of approximately 0.6%. During the first decade of life, the average ECD has been reported to be about 4,640, then it decreases to 2,970 by the age of 30 and continues to decline to 2,400 by the age of 80.

Various performed surgical techniques

Corneal transplantation involves the partial or total replacement of the corneal layers. Currently, the most common type of corneal transplantation is 'penetrating,' which involves grafting a full-thickness corneal button. However, partial thickness grafts or 'lamellar' transplantation are also performed in a significant number of patients. It is indicated for any process lead-

ing to the loss of corneal transparency with preserved neuroretinal integrity and optimal visual potential. Based on the indications, keratoplasties are recommended for therapeutic, tectonic, optical, or cosmetic purposes. Therapeutic keratoplasty is performed to remove the infectious portion of the cornea, mainly in cases of refractory or perforated infectious keratitis. Tectonic keratoplasty provides support and maintains the integrity of the globe. Optical keratoplasty aims to restore vision and has undergone various advancements over time, leading to improved visual quality and postoperative outcomes. Partial removal of the corneal layers, lamellar keratoplasty, has been used to treat anterior corneal scars, keratoconus, and requires a steeper learning curve (3, 4, 5). Rashmi Singh illustrates the types of surgical procedures based on the degree of corneal involvement (4) (fig. 1).

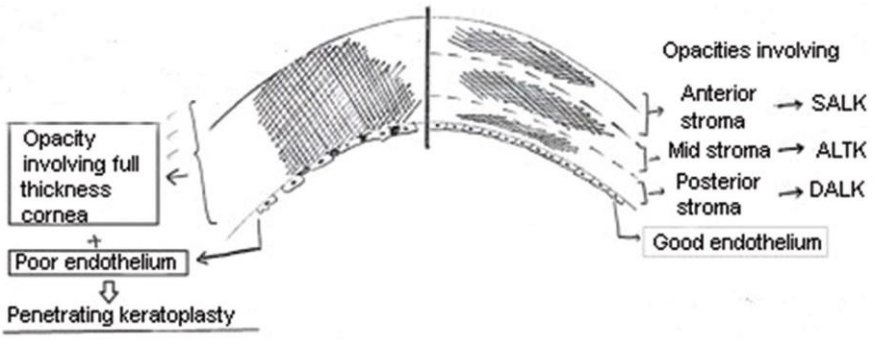

Fig. 1. Diagrammatic representation of the type of keratoplasty depending the on the level of corneal opacities along with endothelial function (Drawn by the authors based on the practical knowledge utilized for decision making in cases of corneal opacity). SALK, superficial anterior lamellar keratoplasty; ALTK, automated lamellar therapeutic keratoplasty; DALK, deep anterior lamellar keratoplasty.

Penetrating Keratoplasty (PK). Zirm successfully performed the first penetrating keratoplasty (PK) in 1905, and until recently, it was the most commonly used corneal transplant technique globally. Due to the rapid implementation of new approaches such as anterior lamellar keratoplasty, the proportion of PK grafts has decreased from 45% to 27% in the last 10 years in the UK. Currently, the most frequent indications are advanced keratoconus not amenable to DALK, tectonic grafts for acute ulcers or infectious keratitis, and the failure of a previous graft. Being the most common procedure for corneal transplantation, PK is generally a successful and efficient treatment for improving visual function. Studies show a graft survival rate ranging from 90% at 5 years to 70% in some studies at 10 years. Failure depends on several factors, primarily the loss of endothelial cells in the donor cornea, with studies reporting a progressive loss over a 10-year post-PK period, leading to late graft failure (1, 2, 4, 5, 9, 10, 11, 12, 13, 14).

Lamellar keratoplasty (LK). During this procedure, the cornea is removed either

superficially (SALK) or deeply (DALK). The clear benefits of this procedure include avoiding complications from open globe surgery (expulsive hemorrhage and endophthalmitis), efficient use of a single cornea, and faster patient recovery (8, 9). Superficial Anterior Lamellar Keratoplasty is indicated for anterior stromal scars after infections, corneal dystrophies, and traumas. It is used for scars occupying 30-40% of the corneal thickness. It is a sutureless surgery that replaces the scar with a graft thickness of 200 μm (4, 5). Deep Anterior Lamellar Keratoplasty (DALK) is performed in cases of deep anterior corneal opacities with good endothelial function, in keratoconus, and certain types of stromal dystrophies. There are two types: pre-Descemet and Descemet's. The pre-Descemet type is done when the cornea is very thin, and there is a risk of perforation. The Descemet's type aims to completely remove the stroma. Many techniques, described using dissection under air or under viscoelastic, have significantly reduced the surgery time and increased the safety of surgical performance (4, 5, 15, 16, 17). A recent meta-analysis comparing the efficiency and safety of DALK vs PK in keratoconus found that the failure rate was similar, but fewer postoperative complications occurred in the DALK group, indicating that, compared to PK, DALK has lower efficiency but higher safety, as demonstrated by other studies (15, 18). Massimo Busin, in a study conducted on patients with keratoconus, used the DALK technique but with the removal of a 6mm central stromal area in 80 eyes without deep stromal scars. In keratoconic eyes without deep stromal scars, combining a larger graft than conventional ones with limited removal of the deep stroma can improve the visual and refractive outcomes of DALK while minimizing the complication rate (19).

Posterior Lamellar Keratoplasty (Endothelial), DMEK, DSAEK. This was described by Melles *et al*. in 1998, involving the total replacement of the posterior area of the affected cornea without affecting the anterior cornea, through a 9 mm limbal incision. Since then, the technique has undergone several improvements. Currently, Descemet's Stripping Automated Endothelial Keratoplasty (DSAEK) represents the current type of the technique, a technically demanding procedure (though less than PLK) that uses a microkeratome to prepare a posterior lamellar donor button, for which the dysfunctional host endothelium is exchanged through a 5 mm scleral tunnel. Once placed and correctly oriented, the graft is pressed anteriorly onto the host's posterior stroma with an air bubble (the pupil is dilated to prevent pupillary block), and the patient maintains a supine position for 24 hours to allow the air bubble to press the graft anteriorly. The advantages of this technique are that visual recovery is faster, it is a closed-globe surgery, avoiding complications like expulsive hemorrhage, but it is challenging to perform. Long-term studies have found that long-term survival rates for DSAEK are comparable or better than for PK. The majority of single-center studies have shown a graft survival rate of 93% or higher at 5 years after DSAEK (1, 5, 6, 20).

The aim of this study is to present our clinic's experience with patients who underwent and were diagnosed with corneal pathologies through the penetrating keratoplasty technique and the medium and long-term therapeutic difficulties encountered in these patients.

MATERIALS AND METHODS

We conducted an observational, retrospective, descriptive study on a series of patient cases who underwent penetrating keratoplasty, focusing on the diagnosis but especially on the difficulties in managing the medium and long-term postoperative care of patients with corneal transplants.

TABLE I.
Surgical and Postoperative Protocol for Corneal Transplant

Disease/Condition	Operative Protocol	Postoperative treatment	Particularities
Keratoconus stage IV Keratoglobus Macular dystrophy Chronic corneal edema Bullous keratopathy Sequela after infectious keratitis	-Decontamination of the periocular skin with 10% Betadine and in the conjunctival sac with 5% Betaine. -Trephination of the donor button with a trephine of the appropriate size after measuring the acceptor patient's cornea with the keratometer. -Marking the acceptor's cornea in 8 or 16 points. -Trephination of the acceptor's cornea. -Excision of the corneal button with left-right scissors. -Injection of miotic and viscoelastic into the anterior chamber (AC). -Fixation of the donor cornea to the recipient bed with 8 or 16 separate sutures, and/or 10.0 Nylon interrupted suture. -Subconjunctival injection with antibiotic + anti-inflammatory and mydriatic.	- Antibiotic and anti-inflammatory eye drops instilled x6/day. - Epithelialization-promoting eye drops and gel instilled x6/day. - Oral corticosteroids 1mg/kg/body in situations at risk of rejection.	- In case of post-herpetic infectious keratitis, add acyclovir 400-800 mg x 5/day. - In patients with keratoglobus: Perform a wide trephination of the cornea (donor diameter 8.25 mm) of the acceptor to avoid the area of large protrusion. -Corticosteroid therapy is essential to prevent graft rejection; sometimes it has been stopped to facilitate epithelialization.

The procedures were evaluated. The inclusion criteria generally followed the recommendations of the national and European transplant guidelines, including: patients with central corneal opacities, keratoconus, corneal dystrophies, with or without intraocular lens implantation, chronic corneal edema, bullous keratopathy, sequelae after infectious keratitis, and keratoglobus. Patients with probable visual potential were included. The surgery was performed by the same surgeon (Dorin Chiseliță) with over 15 years of experience between 2020-2022 and another surgeon (Nicoleta Anton)

in 2024. The surgical technique involved in penetrating optical keratoplasty aimed at functional rehabilitation and improving the quality of patients' life. These patients were registered on the transplant list and monitored, fully evaluated ophthalmologically and for associated general pathologies. All underwent a complete ophthalmological examination, consisting primarily of a detailed medical history related to the ocular pathology. The patients were fully evaluated on equipment and systems, ophthalmologically, being prepared for the surgical procedure under general anesthesia, following the standard follow-up protocol: a comprehensive ophthalmological evaluation involving visual acuity determination, intraocular pressure (IOP) measurement, anterior segment examination and fundus bio microscopy, corneal topography, ocular biometry, ORA, B-mode ocular ultrasound, chromatic sense, ocular motility, tests to detect dry eye syndrome (Schirmer 1, BKT), and OCT (optical coherence tomography) examinations of the optic nerve and macula, as well as interdisciplinary evaluation within the pulmonology and cardiology departments. The operative protocol consisted of penetrating keratoplasty (PK) surgical procedure under general anesthesia and followed the stages that we will detail in first table.

Ethical Approval. During the study, the principles of the Helsinki Declaration were observed. Patients have signed an informed consent, which was attached to the observation sheets.

The postoperative protocol consisted of a series of operative steps and a postoperative protocol according to first table.

Statistical analysis

The data were centralized in a *Micro Soft Excel* database and processed with statistical functions suitable for them, at a significance threshold of 95%.

Simple linear regression allows the study of the relationship between two variables: Y (e.g., number of cases) and X (e.g., time). This linear relationship is graphically illustrated by a regression line according to the formula $Y = a + bX$ (where "b" is the slope of the line, and "a" is the rate at which Y changes at each interval of variable X). The χ^2 test is a non-parametric test that compares 2 or more frequency distributions from the same population, applied when expected events are mutually exclusive. Sometimes, when a frequency in the calculation formula is low, Yates correction is applied to get a higher estimate of the difference. If the p-value is less than the tabular one at the 95% significance threshold, events are not mutually exclusive - in this case, the question arises whether they are dependent. Relative Risk (RR) is the ratio between the risk in exposed patients and the risk in unexposed ones, where the risk in exposed patients is the probability that an exposed individual will develop the disease.

RESULTS

Between 2020 and 2024, in our clinic, the surgeons performed a total of 53 penetrating keratoplasties (16 in 2020, 19 in 2021, 14 in 2022 and 4 in 2024). Apparently, the number of transplant cases over the past 5 years shows a decreasing trend for the upcoming period ($y = 24 - 4x$), but the year 2024 is just beginning and the number of donors is increasing (fig. 2). During the analyzed period, the frequency of female cases was slightly higher (50.9% *vs.* 49.1%), but in 2024, a higher frequency of male cases is noticeable (75% *vs.* 25%; $p = 0.285$).

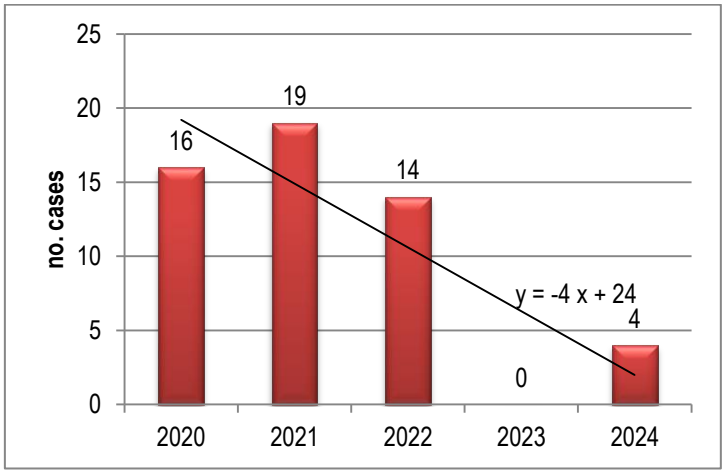

Fig. 2. The number of transplant cases in the period 2020-2024

The number of keratoplasties is due to the small number of donors since Romania did not have a cornea bank during this period. During the analyzed period, the number of complications was not very high, with the most frequent ones being represented by post-traumatic or post-infection corneal leukoma and corneal edema secondary to pseudophakia (fig. 3).

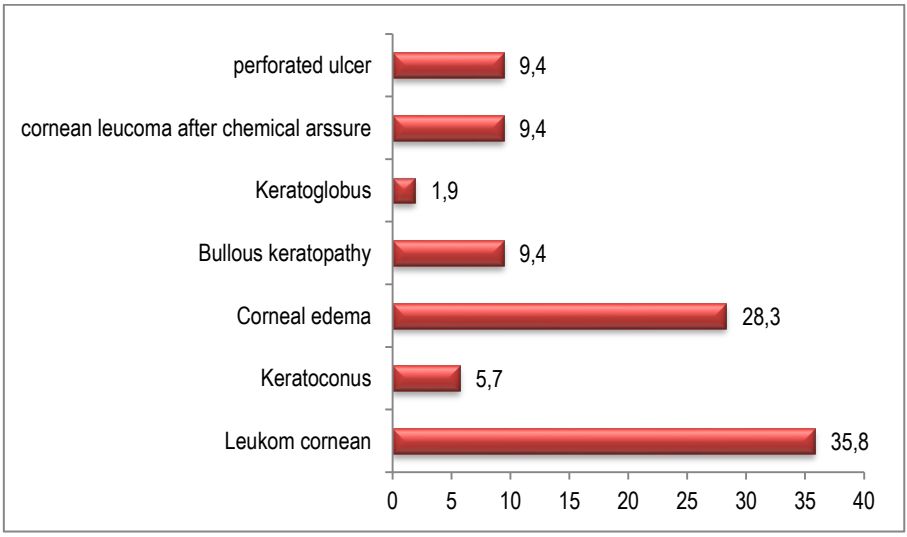

Fig. 3. Pathologies associated with corneal transplantation

From January 2020 to April 2024, a total of 53 keratoplasties were performed, 27 females and 26 males, aged between 16 and 71 years. For this study we selected cases that required special monitoring precautions and needed personalized treatments

and appropriate follow-up. Only 8 out of 53 keratoplasties presented postoperative complications, with one having a severe complication of endophthalmitis leading to enucleation of the eyeball (fig. 4). However, it was found that the risk of complications did not significantly increase in any of the study years (tab. II).

TABLE II.
Distribution of complications over follow-up years

Year	Complications (n=8)		No complications (n=45)		Chi² test	RR	CI 95%
	n	%	n	%			
2020	2	25.0	14	31.1	0.731	0.77	0.17-3.42
2021	4	50.0	15	33.3	0.370	1.79	0.50-6.35
2022	1	12.5	13	28.9	0.920	0.40	0.05-2.95
2024	1	12.5	3	6.7	0.325	1.75	0.28-10.91

The cases selected 2022 had the following pathologies: 2 cases of central corneal leucoma, sequelae of herpetic keratitis, 2 cases of chronic corneal edema in pseudophakia, 1 case of keratoglobus associated with dry eye syndrome and sleep apnea syndrome, corneal dystrophies (3 cases, 1 of Fuchs endothelial dystrophy stage II and 2 of granular), 2 cases after vascularized corneal leucoma secondary to chemical burn, 1 case of corneal leucoma after severe ocular trauma, 2 cases of corneal leucoma, bullous keratopathy, and 2 cases of chronic corneal edema in pseudophakia, associated with pseudo exfoliative and secondary glaucoma. Given these complex cases, surgery is performed under general anesthesia, and special precautions are taken to assess associated general comorbidities.

Case 1 is a 32-year-old patient with a history of ocular chemical burn (var), total vascularized corneal leucoma, trichiasis, and symblepharon for which a KP was performed. Despite appropriate treatment, he experienced early graft failure due to graft opacification secondary to limbal stem cell deficiency and recurrent corneal erosions. The patient did not attend regular follow-up appointments (fig. 4). What is particular about this case is the limbal stem cell deficiency secondary to the burn that contributed to graft failure despite intensive treatment with topical and systemic corticosteroids.

Fig. 4. Graft failure in a patient with corneal transplant, with a history of chemical burn with lime (personal casuistry)

Case 2. A 29-year-old female patient with a history of corneal leucoma post-herpetic keratitis and amblyopia. She underwent penetrating keratoplasty for aesthetic purposes. In addition to standard treatment, she received prophylactic treatment with acyclovir, initially 2 grams per day for a month, followed by a maintenance dose of 400 mg/day, which she continues to take at present. Figure 5 presents the biomicroscopic status before and the day after the transplant.

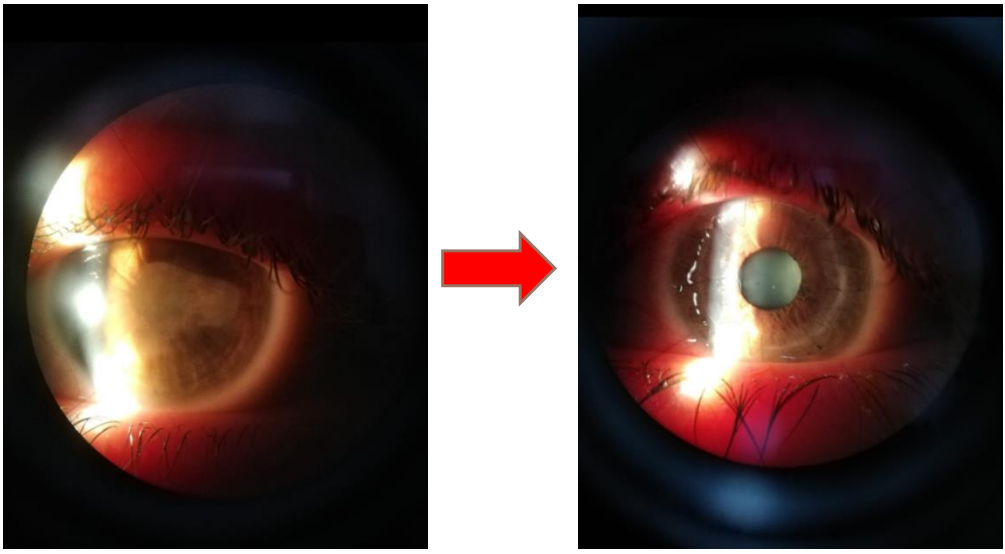

Fig. 5. Images from personal case studies before and after transplant (personal casuistry)

After the first 3 months, the first four interrupted sutures are removed, and all sutures are removed at 1 year. At 1 years and 6 months post-transplant, the evolution is favorable, with vision improving to 0.1 due to keratoplasty, while still keeping up with the dose of acyclovir at 400mg/day (fig. 6).

Case 3 involves a patient known for advanced PEX glaucoma who underwent surgery on the left eye (OS) with visual acuity with hand motion perception (HM), OS pseudophakia due to cataract surgery, and chronic corneal edema in pseudophakia on the right eye (OD). This is a single-eye keratoplasty with favorable postoperative evolution. As a particularity, it required postoperative glaucoma management with continued topical and systemic antiglaucoma medication. The maximum visual acuity achieved is 0.1 without correction, due to severe glaucomatous damage (fig. 7).

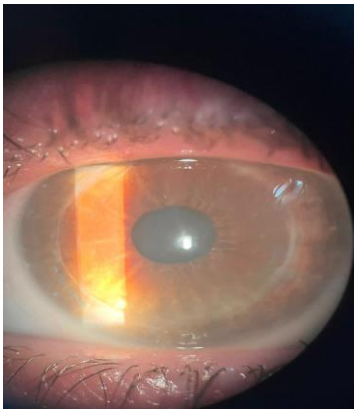

Fig. 6. Clinical status at 1 years and 6 months post-KP (Personal casuistry)

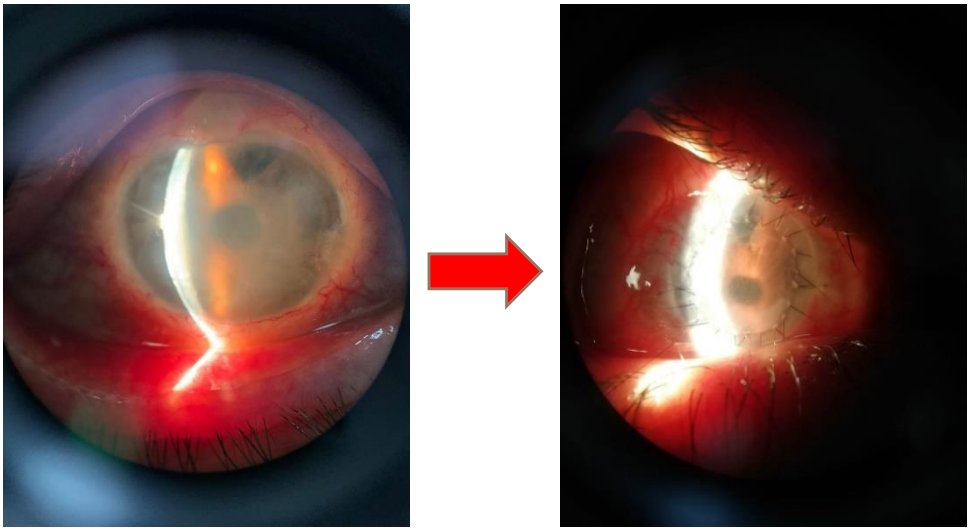

Fig. 7. Clinical status before and after KP (penetrating keratoplasty) (personal casuistry)

Case 4 is that of a 28-year-old female patient with a history of granular corneal dystrophy who underwent keratoplasty in 2020 on the right eye (OD) and in April 2022 on the left eye (OS). An 8 mm corneal button was used, and the evolution was favorable during the first 10 days (fig. 8).

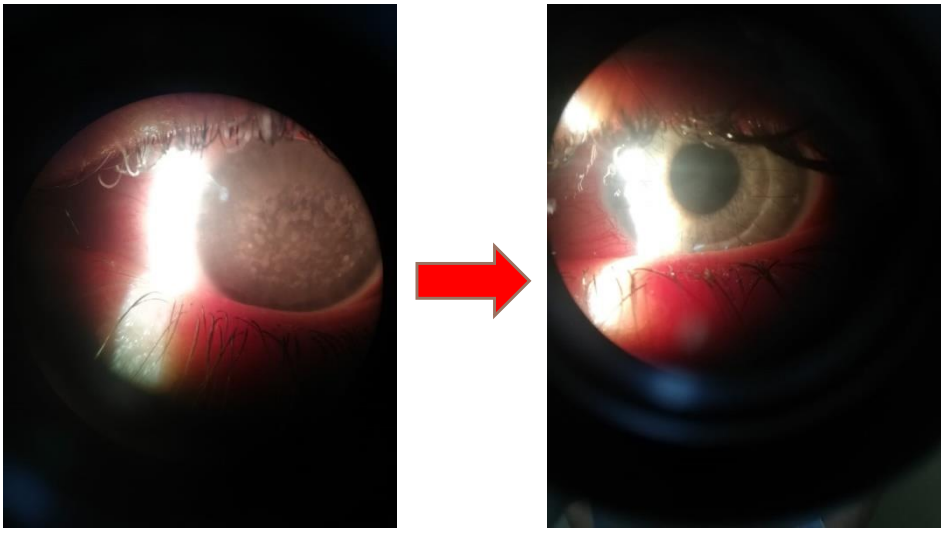

Fig. 8. Clinical status before and after PK (penetrating keratoplasty) (personal casuistry)

A corneal erosion on the graft is made after 30 days, the fluorescein test is positive, and intensive treatment with antibiotics and frequent corneal epithelialization is required. Healing is slow but favorable, with persistent opacity in the lower part of the graft. Her vision remains fairly stable at 22 months post-surgery (fig. 9).

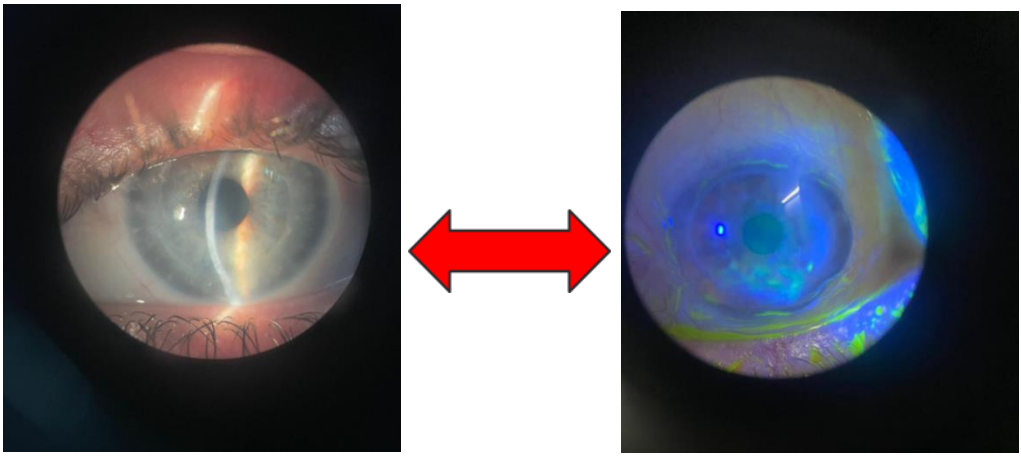

Fig. 9. Clinical status at 22 months post-KP (keratoplasty) (personal casuistry)

Case 5. A 71-year-old male patient from a rural area with Keratoglobus underwent keratoplasty (KP) and was admitted to the Ophthalmology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital in Iași with the following personal pathological history: severe obstructive sleep apnea syndrome, stage II obesity, chronic painless, ischemic heart disease, essential stage II hypertension with increasingly high additional risk, ventricular extrasystolic arrhythmia, aortic cross ectasia, chronic heart failure class II NYHA, hypertriglyceridemia, hepatic steatosis, operated prostate adenoma, bilateral primary gonarthrosis, and bilateral primary coxarthrosis. Ophthalmological examination revealed several pathological aspects: reduced vision in the left eye (OS), severe dry eye syndrome, a diffusely thinned cornea from limbus to limbus in the left eye, its protrusion with a globular appearance, anterior and posterior cortical opacities, and floppy eyelid syndrome (fig. 10).

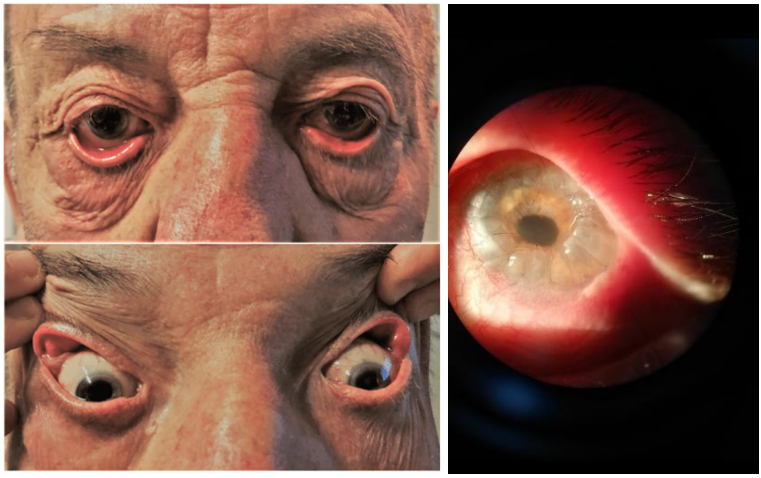

Fig. 10. Clinical status at the beginning, before and after penetrating keratoplasty surgery (personal casuistry)

In addition to the clinical examination and the tomographic examination of the left eye, the diagnosis of Keratoglobus is also significantly influenced by the marked thinning of the cornea across its entire surface (minimum 265 μm) (fig. 11), along with diffuse, concentric bulging, suggestive of the diagnosis. Penetrating keratoplasty was performed along with "open-sky" lens extraction and placement of a multipiece intraocular lens in the capsular bag, with a favorable outcome.

According to the protocols known in corneal transplant surgery, interdisciplinary evaluations are conducted for precise diagnosis, appropriate treatment, and surgical procedure under general anesthesia. The general evaluation also revealed severe obstructive sleep apnea syndrome (Saturation Index = 33.2/hour).

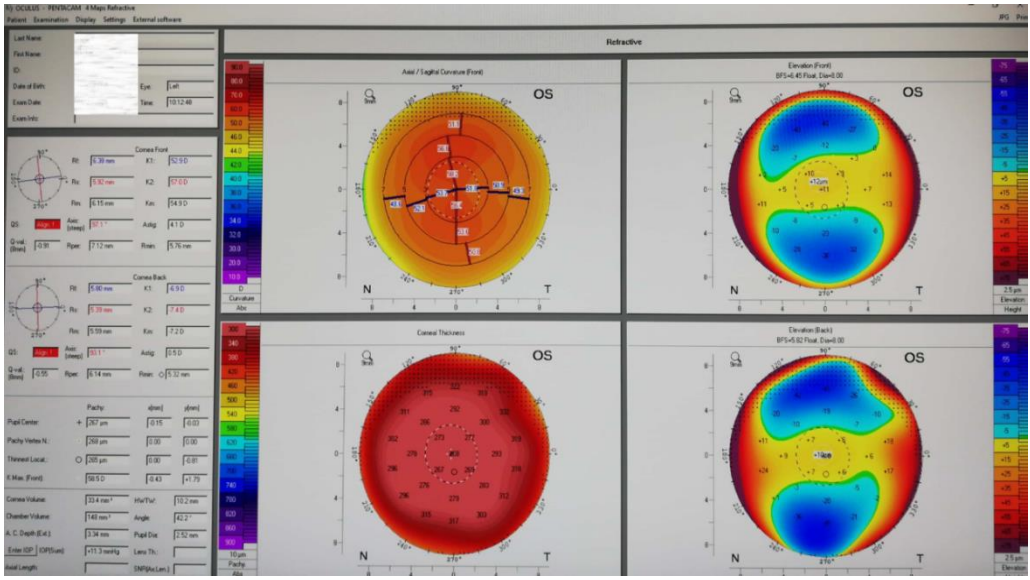

Fig.11. Corneal topography of the left eye (OS). Marked thinning of the cornea across its entire surface (minimum 265 μm) (personal casuistry)

Among the surgical peculiarities, we note the creation of a larger corneal button (8.25 mm) and a slightly decentered trephination due to the specific changes of keratoglobus. The evolution was favorable, and after the removal of the sutures at 1 year, a stable visual acuity was achieved. The cornea fixes diffusely, at 22 months, with a visual acuity of 0.1 without correction. The patient is under chronic treatment with preservative-free artificial tears and epithelializing gels (fig. 12). This patient has associated pathologies requiring both ophthalmological, cardiological and pneumological evaluation. He needs to lose weight and requires positive pressure ventilation 4-14 MB ARR, on a facial mask, for a minimum of 5 hours per night, indefinitely, with respiratory equipment control at 1, 3, 6, 12 months, then annually. Ophthalmologically, it is difficult to quantify the mid and long-term prognosis due to the association of systemic conditions but especially due to the sleep apnea syndrome.

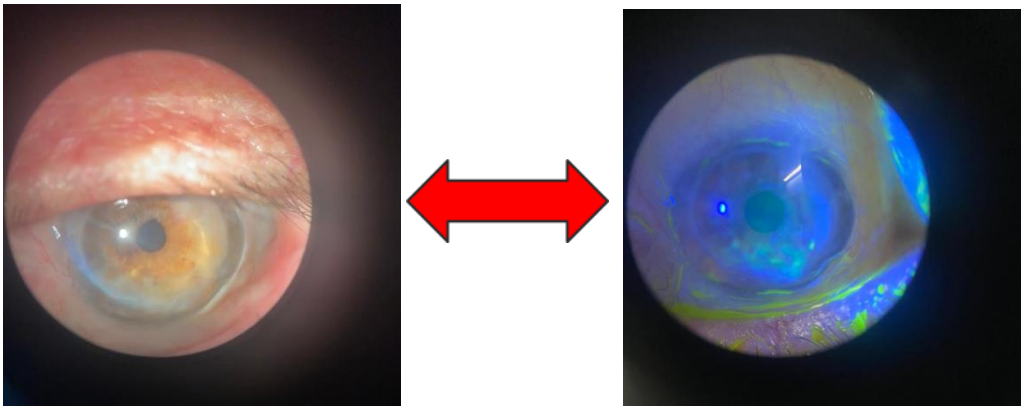

Fig. 12. Clinical status at 22 months post-KP (keratoplasty) (personal casuistry)

DISCUSSION

Corneal transplantation, or keratoplasty, is considered the most successful tissue transplant, largely due to the cornea's "privileged immune" status, which allows a much lower risk of allograft rejection compared to solid organ transplantation. Penetrating keratoplasty (PKP) has become a highly successful procedure due to advancements in eye surgery, corneal surgery, and postoperative treatment. The success of PKP, more than any other ophthalmic surgical procedure, depends on careful and diligent postoperative care. Both the patient and the surgeon must be vigilant about ocular changes so that issues can be promptly addressed and prevent corneal graft failure (19-21). This study highlights the challenges we face in following up with transplant patients and outlines the therapeutic approach in certain situations. When discussing penetrating keratoplasty, the risk of complications is quite high, and the postoperative recovery time is relatively long, sometimes taking years to achieve the best corrected visual acuity. There is a higher risk of allograft rejection compared to other types of keratoplasty, as well as a greater risk of wound dehiscence throughout life due to compromised tectonic resistance stemming from a full-thickness wound. Literature studies show a range of outcomes and complications of penetrating keratoplasty. This procedure is mainly indicated for corneal leukomas, bullous keratopathy, perforated ulcers (2, 21-23) (tab. III).

TABLE III.

Indications for keratoplasty in patients submitted to corneal transplantation

Instructions for KP surgery	Frequency	Studies
Pseudophakic / Aphakic bullous keratopathy	~ 50% of the cases	2, 21, 22, 23
Leucomatous corneal opacity	35-40%	2, 21, 22, 23
Keratoconus and ectasias	1%	2, 21, 22, 23
Impending perforation	8%	2, 21, 22, 23
Melted/Non healing Corneal Ulcer	<1%	2, 21, 22, 23
Perforated Corneal Ulcer		2, 21, 22, 23
Corneal Abscess		2, 21, 22, 23
Failed Corneal Graft	1%	2, 21, 22, 23

Complications of keratoplasty can occur immediately postoperatively or at a distance, and early recognition and treatment are necessary. Therefore, it is extremely important to evaluate on slit-lamp for wound integrity, epithelial defects, corneal edema, IOP (intraocular pressure), iritis, and the possibility of infection on the first postoperative day. Anterior segment OCT examination: CCT (central corneal thickness), ICA (anterior chamber angle depth), and the host-graft junction. As soon as any of these complications manifest or persist, evaluation of the operated eye should be continued daily for a few more days. In table IV, we present possible early and late complications that may occur after penetrating keratoplasty (13, 24-30).

TABLE IV.
Early and late complications after penetrating keratoplasty

Early complications	Late complications
Wound leak	Steroid - induced glaucoma
Primary endothelial failure	Suture - related
Persistent epithelial defect	Infection
Ocular hypertension	Breakage
Urrets-Zavalia syndrome	Irregular astigmatism
Infections	Rejection
Keratitis	•Epithelial
Endophthalmitis	•Stromal
	•Endothelial
	Recurrence of primary disease

Although excellent survival and visual results have been reported for both penetrating and lamellar keratoplasty in the short-term, there are a limited number of published multicenter studies on long-term outcomes. According to literature studies, the graft survival rate is quite high. The graft survival outcome for optical purposes at one and three years is 91.7% and 75.8%, respectively. The Australian Corneal Registry Study (ACGR) reported that the survival of penetrating corneal grafts was 62% after ten years (13, 23, 24). In our patients, out of 14, one presented early graft failure due to limbal stem cell deficiency, secondary to burns which favored graft failure despite intensive topical and systemic corticosteroid treatment. Some cases had a slow favorable evolution. The other cases had a series of complications related to inadequate treatment, frequent graft erosion, corneal ulcer which, after appropriate treatment, had a favorable evolution. One case where we performed a recent transplant had a suture breakage and required reevaluation and treatment. A recent meta-analysis on the incidence of wound dehiscence after keratoplasty showed, from a selection of several articles, that the overall incidence of wound dehiscence was estimated to be 1.9% (95% CI: 0.03, 0.26). Of the included studies, six focused on PK involving 5,611 patients, while three trials examined DALK with a total of 2,101 patients. The analysis revealed that patients undergoing PK were more than twice as likely to experience wound dehiscence compared to those undergoing DALK (25,

26). Other complications described by specialized literature studies include the occurrence of glaucoma. Different studies showed a variable incidence of glaucoma after PK, ranging from 9 to 31% early postoperatively and from 18 to 35% in the late postoperative period. Steroid-induced IOP elevation was the most frequent cause, with an incidence of 38.3%. The most important risk factors in the occurrence of post-PK glaucoma are the lens status (aphakia, pseudophakia) and the disease for which the PK is performed (27, 30, 31). The functional success of a corneal graft depends on many variables, including good surgical technique with adequate donor and host integration, immunological acceptance of foreign tissue, a functional level of astigmatism, and a smooth corneal surface supported by ocular annexes. Corneal infection (keratitis), whether active or healed after keratoplasty, is a major complication that can jeopardize the graft result, leading to failure and poor visual outcome, being a major cause of graft rejection. Microbial keratitis on the graft can occur at variable times after keratoplasty. Studies have reported that most graft infections usually occur within one year of corneal transplantation. Early postoperative infection can occur due to recurrence of the host's disease, infected donor cornea, or intraoperative contamination. Usually, late infections are caused by pathogens acquired from the surrounding environment. The median interval between penetrating keratoplasty and microbial keratitis was 7.6 months. Aggressive corticosteroid treatment in the first six months is a contributing factor to the onset of infections (13, 24). Among late complications, astigmatism is the most frequent cause of suboptimal vision after corneal transplantation despite a clear corneal graft. Based on several studies, 15-31% of patients undergoing PK may develop postoperative astigmatism greater than 5 diopters. Keratometry, photo-keratoscopy, slit-lamp examination, and manifest refraction help in the identification of any tight sutures. Selective suture removal has been shown to hasten visual rehabilitation. Selective suture removal begins at about 6 weeks, and only one or two sutures are removed at one time. The cornea is evaluated every 2 weeks for change in contour, and further sutures are removed (28, 29).

CONCLUSIONS

Although, in terms of survival, corneal transplantation is the most successful transplant performed in humans, rejection is still the main cause responsible for graft failure. Keratoplasty involves a long healing process; therefore, preoperative evaluation and dialogue with the patient are important to understand the benefits, possible complications, and the need for prolonged treatment. Corneal transplantation represents a challenging surgery both in terms of surgical technique and preoperative evaluation and postoperative management.

The alignment of diameters between the host cornea and the donor cornea plays an essential role in centering and ensuring the survival of the transplanted graft.

Suturing techniques are standardized, but the particularities of each case should always be considered, which may require an adapted approach (individual sutures *vs.* continuous suture).

The functional prognosis depends on the patient's condition, the surgery itself, the patient's compliance with treatment and

recommendations, and also on the doctor-patient relationship.

For long-term success after keratoplasty, it is desirable for both the surgeon and the patient to be constantly vigilant to ocular changes so that issues can be promptly addressed. Caring for the corneal transplant is a lifelong commitment. Good interdisciplinary cooperation leads to an increased success rate.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

CLINICAL, BIOLOGICAL AND SOCIAL CHARACTERISTICS ASSOCIATED WITH POSITIVE AND NEGATIVE SYMPTOMATOLOGY IN SCHIZOPHRENIA AND BRIEF PSYCHOTIC DISORDER (Abstract): Psychotic disorders are prevalent mental health conditions that frequently go underdiagnosed, particularly in their early stages. During the prodromal period, symptoms are frequently underestimated or misattributed. **Materials and methods:** We collected data from the "Socola" Institute of Psychiatry, gathering information from 392 patients hospitalized in 2023 and diagnosed with brief psychotic disorder or schizophrenia. We analyzed classification by age group (20-40, 40-60, and ≥61 years old), rural or urban living environments, level of education, association with depression or anxiety using the Hamilton scales, presence of other psychiatric comorbidities, suicidal ideation or attempts, presence of inflammatory markers (ESR, CRP, and leukocytes), and the treatment plan. **Conclusions:** Our study provided a detailed demographic and clinical profile of patients with brief psychotic disorders and schizophrenia at the "Socola" Institute. The findings highlight the importance of an integrated approach to assessment and management, emphasizing early identification of risk factors and implementation of preventive interventions to promote healthy living and prevent chronic disorders. **Keywords**: PSYCHOSIS, SCHIZOPHRENIA, BRIEF PSYCHOTIC DISORDER, MORTALITY, MEDICATION NON-COMPLIANCE.

Psychotic disorders are common mental disorders, often underdiagnosed, especially in the early stages. The prodromal period is frequently underestimated or misclassified. According to the Global Burden of Diseases, schizophrenia affects 20 million people worldwide, with 1.5 new cases per 10,000 people annually. The World Health Organization (WHO) ranks psychotic disorders among the top 15 causes of disability. Approximately 5% of individuals with at least one psychotic episode commit suicide, while 20% attempt suicide (1).

The costs of treating psychotic disorders exceed those for high blood pressure and diabetes combined. In about 10% of

schizophrenia cases, psychotic decompensations occur within a year, even with monthly monitoring. Early intervention and appropriate treatment in the initial phases are crucial for medication compliance and establishing a therapeutic alliance (2).

The link between the immune system and the brain was established in 1985, with studies showing suppression of immune response in depression. Elevated levels of inflammatory markers are found in patients with major depressive disorder, even without a somatic condition. The coexistence of depression with inflammation and the increased risk of depression with cytokine treatment suggest inflammation's role in depression's pathogenesis (3).

Recent studies indicate a connection between inflammation and psychiatric disorders, particularly schizophrenia. Increased inflammatory markers, such as interleukins (IL-6, IL-1β) and tumor necrosis factor alpha (TNF-α), are found in patients with major depressive disorder and schizophrenia (4-6). Psychological stress can increase pro-inflammatory cytokines, and inflammation may mediate the relationship between diet and mental health, suggesting a high-fiber diet may reduce inflammation and psychotic symptoms (7-9).

Understanding the interactions between the immune system and the brain has significant implications for treating and preventing neuropsychiatric disorders. Recent findings on the link between inflammation and psychosis open new research directions and potential therapeutic approaches (10).

MATERIALS AND METHODS

The study aims to explore the role of inflammation in the pathogenesis of psychotic disorders, particularly schizophrenia. A key objective is to investigate the association between inflammatory markers, such as interleukins (IL-6, IL-1β) and tumor necrosis factor alpha (TNF-α), and the severity of psychotic symptoms.

Another goal is to analyze how inflammation influences treatment response in patients with psychosis. This aspect aims to determine if patients with elevated inflammatory profiles benefit differently from various therapeutic interventions, including antipsychotic treatments and anti-inflammatory strategies.

The study also examines the impact of environmental factors, such as diet and stress, on inflammation and mental health. This includes evaluating how dietary changes, such as adopting a high-fiber diet, might affect inflammation and the severity of psychotic symptoms.

Methodologically, an integrative approach will be used, combining clinical and biological data to understand the interactions between the immune system and the central nervous system in psychotic disorders. This research could lead to new perspectives in treating and managing neuropsychiatric disorders, promoting the development of more effective and personalized therapeutic strategies.

After obtaining the consent of the "Socola" Institute's management, we accessed the electronic databases to identify patients hospitalized in 2023 and diagnosed with brief psychotic disorder or schizophrenia. We selected a total of 392 patients, of which 190 were women and 202 were men.

We classified them by age groups and compared patients from rural areas with those from urban areas and studied their level of education. We also used the Hamilton Depression and Anxiety Scales to determine any association with these disorders and documented the presence of other psychiatric comorbidities. We also assessed

suicidal ideation and suicidal attempts identified in the patient's psychological examination. To complete the analysis, we measured the levels of the inflammatory markers ESH, CRP, and leukocytes, the only relevant laboratory tests available in the "Socola" Institute in 2023, and recorded the types of treatments given to patients.

RESULTS

Analyzing the graph below, we can conclude that there were no major differences between the number of women and men hospitalized in 2023, the percentage being 53% men, compared to 47% women.

Regarding the distribution by age groups, we identified 4 women aged 20-40, 150 women aged 40-60, and 16 women aged over 61 years old (tab. I).

The results presented in second figure indicate a significant rate of psychotic decompensations in women between 40 and 60 years old, which represent 88% of cases. This suggests that women in this age group are particularly vulnerable to decompensated psychotic disorders. Factors that could contribute to this vulnerability include cumulative stress over the years, family and work responsibilities, and possible hormonal changes associated with menopause. Women over 61 years old account for 10% of cases, indicating that although the risk of psychotic decompensation decreases after the age of 60 years old, it does not disappear completely. Age-related health problems, social isolation, and personal loss can contribute to psychological vulnerability in this age group.

On the other hand, women between the ages of 20 and 40 years old have the fewest admissions for psychotic decompensation, accounting for only 2% of cases. This may suggest greater resilience to stress and mental disorders at younger ages or may reflect underdiagnosis or underreporting of these conditions among young women.

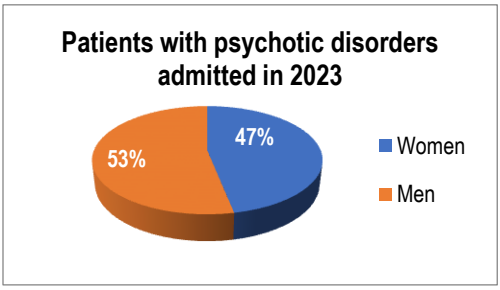

Fig. 1. The ratio of women/men hospitalized in 2023

TABLE I.
Distribution of hospitalized women in 2023 by age group

Age group	Number of women
20-40 y.o.	4
40-60 y.o.	150
≥61 y.o.	16

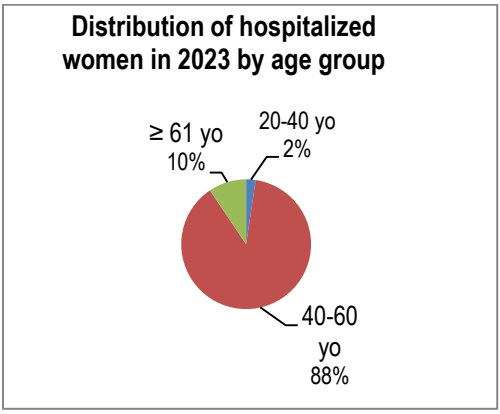

Fig. 2. Distribution of hospitalized women in 2023 by age group

These results emphasize the importance of monitoring and targeted interventions for middle-aged women, who appear to be most affected by psychotic decompensations. It also highlights the need to provide adequate support for older women to help

them manage the psychological challenges associated with aging. At the same time, vigilance must also be maintained for younger age groups to ensure early identification and treatment of mental disorders.

It was found that female patients from the rural area (63%) had a higher hospitalization rate compared to those from the urban area (37%) with a diagnosis of major depressive disorder during 2023 in the Vth Acute Ward of the "Socola" Institute of Psychiatry. This aspect can be explained by the fact that patients from the urban environment have more mental health centers available to which they can go, private offices, outpatient clinics, and perhaps a higher degree of availability and logistical possibilities compared to those from the rural environment for addressing at a doctor in general and psychiatrist in particular (tab. II).

TABLE II.

Distribution according to the environment of origin by age group

Age group	Rural (57)	Urban (33)
20-40 y.o.	4	0
40-60 y.o.	80	70
≥ 61 y.o.	2	14

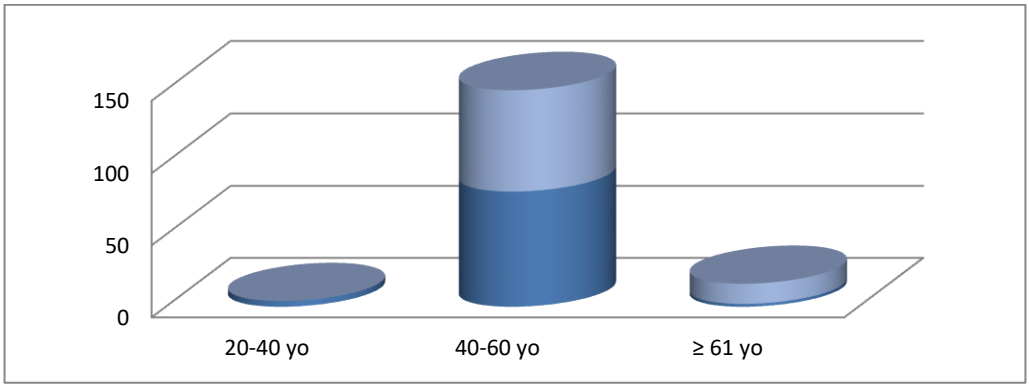

Fig. 3. Distribution by age group and background

Also, a monthly dispensary for a psychiatric condition leads to a decrease in the frequency of relapses, thus making continuous hospitalization less necessary.

Another aspect to consider is the stigmatization of the psychiatric patient, which unfortunately in Romania is still in continuous development, with all the attempts by the employees of the health system and the mass media to counteract it. Stigmatization and public recognition of a psychiatric condition can often delay presentation to a doctor, with patients first often going through many psychological evaluations and therapies, a fact that would perhaps be characteristic of urban patients, more so than rural ones.

At the same time, patients who have changed their residence from the urban to the rural environment may experience depressive symptoms, the rural environment in Romania being considered in most cases, a disadvantageous environment.

Analyzing the graph and the table above (fig. 4) we can see that most of the patients who requested treatment have high school as their last form of education, especially in the 40-60 age group. In contrast, the lowest addressability was registered among patients with higher education, being only 52

in number. This phenomenon can be explained by the fact that, currently, the predominant form of schooling completed in Romania is high school.

	Highschool	Trade school	Higher education
≥ 61 yo	12	2	2
40-60 yo	50	50	50
20-40 yo	1	3	0

Fig. 4. Distribution according to education level by age group

This finding suggests that education level may influence access to and use of health services. People with higher education, although fewer in number in the presented statistics, could have better access to health information and, implicitly, to prevention and treatment services. They could also benefit from better financial resources and a social support network to contribute to more effective mental health management.

In conclusion, this review highlights the importance of education in accessing and using mental health services and the need for targeted interventions to improve addressability among all educational categories, particularly those with lower levels of education.

The Hamilton Depression Rating Scale is the gold standard for depression scales, unrivaled in general psychiatry. This scale is a measure of depression and includes 17 items, rated on 3-5 degrees, and appears to be a good indicator of the global intensity of the depressive syndrome, sensitive enough to appreciate the change under antidepressant treatment. The scale includes evaluation items of cognitive, behavioral, and especially somatic components (fig. 5).

	Severe Anxiety	Moderate Anxiety	Mild Anxiety	No associated anxiety
≥ 61 yo	3	6	6	1
40-60 yo	20	6	4	40
20-40 yo	0	1	0	3

Fig. 5. Distribution according to severity of depression and association with anxiety, using the Hamilton scale

Most of the time, depression is associated with other comorbidities, either psychiatric or somatic. Thus, for example, in women with depression, we identified 35% with emotionally unstable personality disorder, 25% with dependent personality disorder, 14% with panic disorder, 17% with autolytic ideation, 6% with autolytic attempt and 7% with dementia, in which case I consider that obesity was actually secondary to dementia (fig. 6).

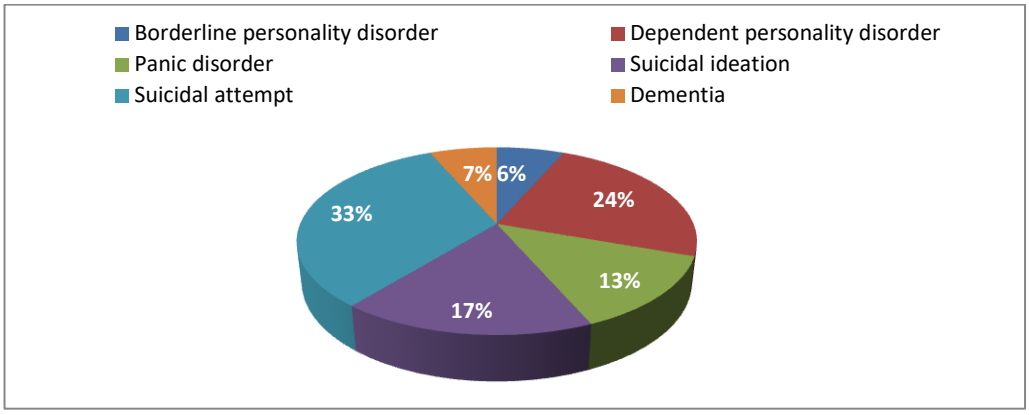

Fig. 6. Associated psychiatric comorbidities

Due to the increase in the suicide rate due to depression, this mental disorder has become one of the most studied psychiatric conditions. Effective management depends on early recognition and diagnosis of depression before it produces suicidal ideation. The clinical diagnosis of depression, beyond the clinical recognition of diagnostic criteria, can be supplemented by the use of specific clinical scales with varying degrees of complexity, from the simplest, such as the MADRS, to the most elaborate, such as the Hamilton scale, which quantifies suicidal ideation. The multidisciplinary approach to depression is reflected in its therapeutic management, from its recognition at the primary ambulatory level to psychiatric evaluation and treatment, with the subsequent recommendation of following a psycho-therapeutic intervention (fig. 7).

The presented results show a clear distribution of patients with autolytic ideation according to age group. In the age group 20-40 years, no patients with autolytic ideation were identified, which suggests that, in this age range, the prevalence of autolytic ideation is very low or nonexistent in the studied sample.

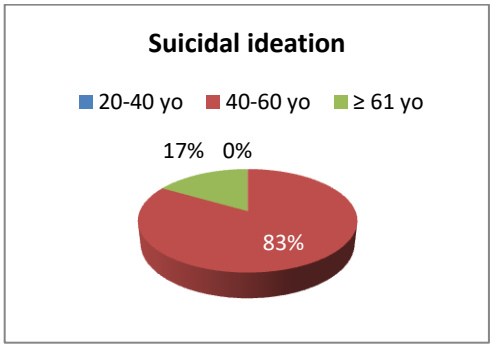

Fig. 7. Association of depression with suicidal ideation

Instead, the 40-60 years old age group is the majority, with a percentage of 78%.

This indicates that women in this age group are most susceptible to autolytic ideation. Possible factors contributing to this vulnerability include work and family stress, menopause, and other hormonal changes, as well as possible health problems and existential crises specific to midlife.

For women over 61, the percentage of autolytic ideation is 22%. Although this percentage is significantly lower than in the 40-60 age group, it still suggests an important concern for mental health among the elderly. Factors such as loneliness, loss of a life partner, health problems, and decreased quality of life may contribute to the increase in autolytic ideation in this age group.

These results emphasize the importance of specific interventions for each age group. For middle-aged women (40-60 years old), psychological support and stress management programs should be developed, as well as mental health monitoring. For older women (over 61 years), it is essential to ensure access to adequate social and medical support, as well as programs to combat loneliness and improve quality of life.

In conclusion, these data highlight the need for personalized prevention and treatment strategies, tailored to the specific needs of different age groups, to reduce the risk of autolytic ideation and improve mental health among women.

The results show that among the cases with associated autolytic attempts, the majority are in the age group of 40-60 years, with 13 patients, while only 3 patients are in the age group of more than 61 years (fig. 8). These data suggest that middle-aged women are more likely to make autolytic attempts compared to older women. The identification of 13 patients with autolytic attempts in this age group suggests a significant vulnerability to psychological and emotional stressors. Possible contributing factors include:

- Stress related to career and family responsibilities;
- Hormonal changes, including menopause, which can affect mood and emotional stability;
- Midlife crises and changes in identity and social roles.

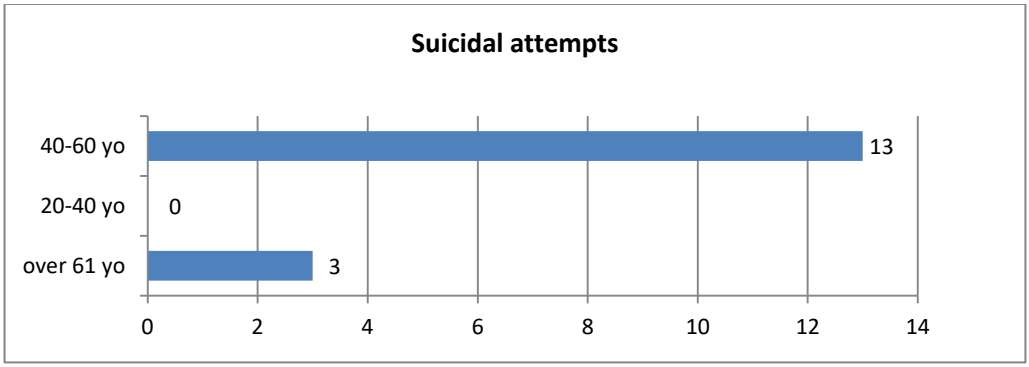

Fig. 8. The association of depression with autolytic attempts

Regarding the identification of 3 patients with autolytic attempts in this age group, although numerically smaller than the 40-60 age group, it is still significant and indicates a mental health problem among the elderly. Possible contributing factors include:

- Social isolation and loneliness, which are common among older people;
- Physical health problems and decreased quality of life;
- Loss of life partner and friends, which can contribute to depression and autolytic ideation.

The results highlight the need for increased attention to the mental health of middle-aged and older women. Tailored interventions that consider risk factors specific to each age group can help reduce autolytic attempts and improve overall well-being.

As particularities in the case of patients who presented suicidal ideation, we encountered in 52% of cases elevated ESR, in 16% of cases CRP at the upper limit, 16% with associated duodenal ulcer, 10% with gastroduodenitis and 6% with GERD (fig. 9).

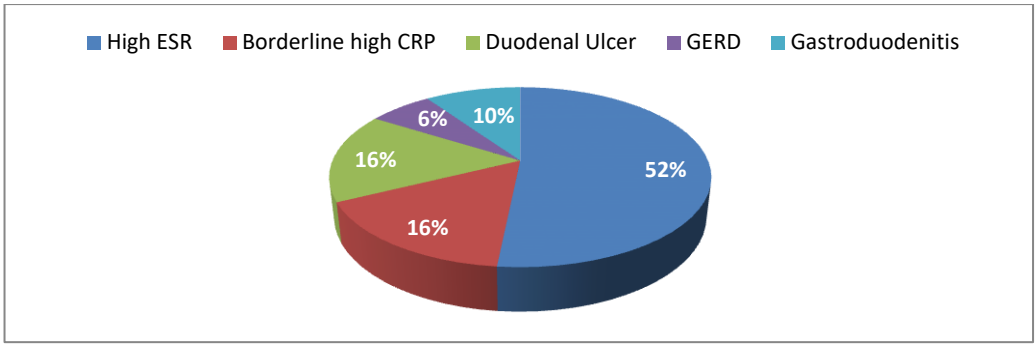

Fig. 9. Peculiarities associated with suicidal ideation

DISCUSSION

Our study identified various inflammatory markers (ESR, CRP, leukocytes) in women with psychotic decompensation hospitalized in 2023. These findings align with recent research on the role of inflammation in psychotic disorders, including schizophrenia. Studies show elevated levels of interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α) in patients with major depressive disorder and schizophrenia (11).

Our results indicate a higher prevalence of psychotic decompensation in women aged 40 to 60 years, supported by studies linking this to hormonal factors, accumulated stress, and family and professional responsibilities (12). In contrast, young women (20–40 years) had fewer admissions, suggesting greater resilience or underreporting of symptoms. Other studies also found an increased risk of severe psychotic symptoms in women aged 40 to 60 years (11, 12).

The majority of hospitalized women were employed or on sick leave, highlighting the role of occupational stress and chronic conditions in psychotic decompensations. Other studies confirm this link, suggesting that psychological support at work can reduce the incidence of these disorders (13). Ehlen *et al.* (2023) emphasized the importance of workplace interventions to reduce stress and improve mental health (14).

Our data show higher addressability among rural women compared to urban women, likely due to reduced access to mental health services and the stigmatization of mental illnesses in rural areas. Studies suggest that telemedicine and public education campaigns can improve access to healthcare in rural areas (15). Mukhamadi-

eva and Shodieva (2021) demonstrated the effectiveness of telemedicine in enhancing access to mental health services in rural areas (16).

Personality disorders and suicidal ideation were frequently identified in patients with depression, consistent with the literature. Studies show that major depression often coexists with other psychiatric disorders, and effective management of these comorbidities and even dietary habits is crucial for suicide prevention (17, 18).

CONCLUSIONS

Analysis of 2023 admissions data for psychotic decompensations showed a slightly higher prevalence in males (53%) compared to females (47%). Among females, women aged 40-60 represented 88% of admissions, indicating increased susceptibility due to factors like work and family stress, menopause, and chronic conditions. In contrast, young women (20-40) had fewer admissions, possibly due to greater resilience or underreporting.

Patients from rural areas had higher admission rates (63%) compared to urban areas (37%) for major depressive disorders. This may be due to limited mental health services and stigma in rural areas. Strategies to improve access, such as telemedicine and public education campaigns, are essential.

Most hospitalized patients had high school education, particularly in the 40-60 age group, while those with higher education were underrepresented. Education level influences access to and utilization of mental health services, with higher education associated with better understanding and resources for managing mental health.

Women aged 40-60 years old were most affected by suicidal ideation (78%), compared to those over 61 (22%). This underscores the need for targeted interventions, including psychological support and monitoring. Autolytic attempts were more common in middle-aged women (13 cases), highlighting their vulnerability to stress.

Biological and clinical features in patients with suicidal ideation included elevated inflammatory markers (ESR), upper limit CRP, and gastrointestinal conditions. These comorbidities suggest a complex interaction between mental and somatic conditions, necessitating a multidisciplinary treatment approach.

Recommendations:

1. Tailored Interventions: Develop psychological support and stress management programs for middle-aged women and improve access for older individuals.

2. Improving Access: Expand mental health services in rural areas and reduce stigma.

3. Education and Prevention: Implement public education campaigns on mental health and promote service utilization across all educational levels.

4. Multidisciplinary Approach: Integrate the assessment and treatment of somatic conditions in managing depression and preventing suicide.

These conclusions highlight the importance of a comprehensive approach tailored to different age groups and socioeconomic categories to improve mental health and reduce psychotic decompensation and suicide risk. The study provides new insights into the determinants of psychotic decompensations and clear directions for developing effective intervention and prevention programs. Continued research is crucial to adapt public health policies to the specific needs of affected populations.

CLINICAL, BIOLOGICAL CHARACTERISTICS, RISK FACTORS AND OUTCOMES IN HUMAN ENTEROVIRUS CENTRAL NERVOUS SYSTEM INFECTIONS: A PROSPECTIVE STUDY PERFORMED IN A TERTIARY HOSPITAL (Abstract): Human enterovirus (HEV) infection is transmitted mainly by the fecal-oral route and has mostly a subclinical, self - limited evolution. This viral central nervous system (CNS)infection could be fatal in various categories of patients. The aim of the current study was to evaluate the clinical-biological characteristics and outcomes of HEV CNS infections in patients admitted to the "Sf. Parascheva" Clinical Hospital of Infectious Diseases Iasi, during 2018-2019. **Materials and methods:** We performed an observational prospective study in patients with confirmed HEV CNS infections (encephalitis / meningitis) by cerebrospinal fluid analysis. Clinical and laboratory data were collected from medical records. **Results:** Sixty - four patients were included, of which 57.81% were diagnosed with HEV encephalitis. All categories of ages were affected, with a median of 67 years in encephalitis and 56 years for patients with meningitis. The most frequent comorbidities were cardiovascular (44.29% cases). The blood neutrophil - lymphocytes ratio (NLR) was statistically significant higher in case of HEV meningitis compared to encephalitis (12.42 ± 4.12 *vs.* 7.97 ± 3.86, p = 0.04). There were significant differences regarding NLR measured in cerebrospinal fluid. The median duration of hospitalization was 5.63 days in HEV encephalitis and 10.92 days in HEV meningitis. There were recorded 23.33% cases of death, all in old, immunosuppressed patients (diabetic patients) with HEV encephalitis. **Conclusions:** HEV CNS infections, are an important cause of mortality in high - risk patients (elderly, immunosuppression). Measurement of NLR could be a useful early diagnostic tool to ensure proper pharmacological management of HEV infections.
Keywords: RISK FACTORS, HUMAN ENTEROVIRUS, CENTRAL NERVOUS SYSTEM, PROSPECTIVE STUDY, TERTIARY HOSPITAL.

INTRODUCTION

Viral central nervous system (CNS) infections (meningitis and encephalitis) are an important cause of morbidity, permanent neurologic sequalae and even mortality among patients. Although they were recorded in all age categories, children and elderly patients, immunocompromised

patients are more strongly affected. The most common etiologies are herpesviruses 1 and 2 (HSV-1 and HSV-2), human herpesvirus 6 (HHV-6), non-polio enterovirus, and arboviruses (West Niles, Zika, dengue, chikungunya), influenza, cytomegalovirus (CMV), Epstein-Barr virus (EBV) (1, 2). Neurological complications, such as encephalitis were reported also in patients with SARS -CoV2 infections (3). Enteroviruses can affect both brain parenchyma and meninges and cause meningoencephalitis.

Diagnosis of enteroviral CNS infections is based on clinical - biological and imagistic data. Medical history, but also history of travel in endemic areas offers useful information to establish a diagnosis.

The International Encephalitis Consortium has proposed the following diagnostic criteria for encephalitis: altered mental status (altered consciousness, personality change) lasting over 24 hours (major criteria) and minor criteria: fever ≥ 38°C, seizures, focal neurological findings, CSF pleocytosis, focal neurological findings on neuroimaging, abnormalities on electroence-phalography without other identified cause (4). However, the criteria proposed have a low sensitivity and specificity of diagnosis, and a new validation score was proposed (5). Clinical features of enteroviral meningitis include triad: fever, neck stiffness and headache. Other neurological symptoms are photophobia and vomiting. Enteroviral CNS infections should be differentiated of other brain infections (brain abscess, other aseptic meningitis caused by *Borellia burgdorferi, Leptospira spp., meningeal tuberculosis, Treponema pallidum, Naegleria fowleri or Cripotccoccus neoformans*), encephalopathy (autoimmune, diabetic ketoacidosis, kidney failure or poisoning) or meningeal invasion in malignancies, autoimmune disorders or drug - induced aseptic meningitis (6, 7). Cerebrospinal fluid (CSF) analysis is the main tool to establish the diagnosis of CNS infection. CSF is clear with pleocytosis (mainly lymphocytes), with high level of proteins and variable levels of glucose depending on etiology. Etiological diagnosis is based on microscopic examination, serological tests (enzyme-linked immunosorbent assay, immunofluorescence, hemagglutination inhibition test) and molecular biology analysis (Polymerase chain reaction, Real-time polymerase chain reaction/qPCR, Reverse transcription polymerase chain reaction/RT-PCR, Nested polymerase chain reaction /nPCR) (1, 2).

The treatment of viral CNS infections is mainly symptomatic and pathogenic. Etiological treatment is available only for infections caused by herpes viruses. However, until a bacterial infection is excluded, antibacterial coverage is used in practical routine (8).

In this context, we conducted a prospective study to assess the clinical-biological characteristics and outcomes of HEV CNS infections in patients admitted to the "Sf. Parascheva Clinical Hospital of Infectious Diseases" Iasi during 2018-2019.

MATERIALS AND METHODS

We performed a prospective observational study which included patients with enteroviral CNS infections. Patients were hospitalized in Clinical Hospital of Infectious Diseases "Sf. Parascheva" Iasi between 2018 - 2019. The study was approved by the Ethics Committee of the hospital, the Ethics Committee of the University of Medicine and Pharmacy "Grigore T. Popa" Iasi. The data was collected in agreement to ensure data protection. The

informed consent was obtained from the patients or their legal representatives before the inclusion in the study.

Inclusion criteria

- written informed consent obtained from the patient or their legal representative
- clinical manifestations: fever, loss of consciousness, photophobia, headache, neck stiffness
- enteroviral CNS infection confirmed by CSF analysis

Exclusion criteria

- other non - enteroviral CNS infections caused by other viruses (including HIV infections)
- bacterial, mycobacterial or fungal CNS infections
- multiple organ dysfunctions
- other non - infectious CNS pathological conditions (cerebral hemorrhage or infarction, malignancies, autoimmune)
- lack of consent of the patients or the legal representative (when applicable)
- patients with incomplete clinical or biological data.

Data collection

Data collected from the medical records included: demographic data (age, gender), medical history, CNS infection history (symptoms at onset, duration), laboratory data (full blood count, CSF analysis, serological tests, PCR), imagistic (cerebral CT), treatment, duration of hospitalization and outcome.

Statistical analysis

Normally distributed data are presented as means ± standard deviations, and nonnormally distributed data are reported as medians and ranges). The chi-squared test was performed for the single-factor analysis of count data and the Kruskal-Wallis was performed for the single-factor analysis of non-normally distributed data. The differences were considered statistically significant at $p < 0.05$. Statistical analysis was performed using XLSTAT 2023.

RESULTS

A total of 64 eligible patients with HEV CNS infections (encephalitis or meningitis) were included in our analysis. Of these, viral meningitis was noted in 61.42% cases, mainly in males (ratio male / female of 3 in meningitis and 1.5 in encephalitis) (fig. 1).

All age groups were affected, the median age being 67 years (23 - 88 years) in HEV encephalitis, respectively 56 years (range 2 - 87 years) in HEV meningitis (tab. I).

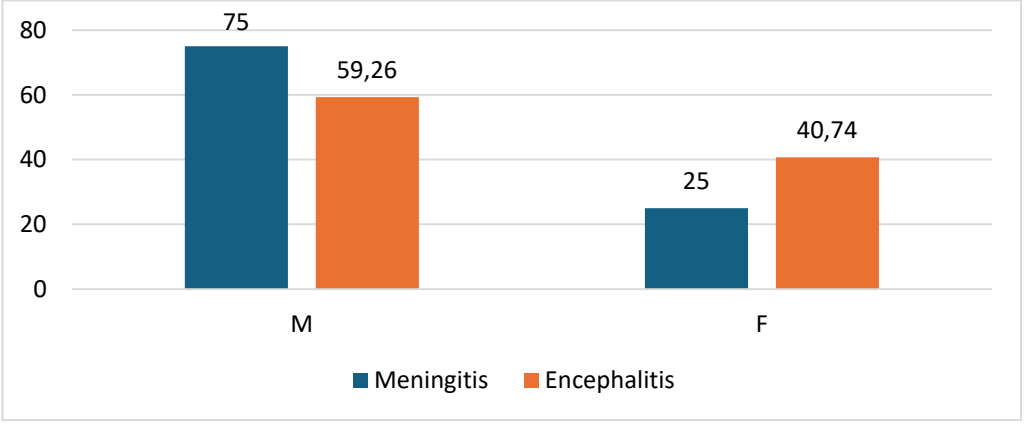

Fig. 1. HEV CNS infections - gender repartition (%)

TABLE I.
Demographic characteristics of patients with HEV CNS infections

	Age (years)		Height (cm)		Weight (kg)	
	Encephalitis (N = 27)	Meningitis (N=37)	Encephalitis (N = 27)	Meningitis (N=37)	Encephalitis (N = 27)	Meningitis (N=37)
Average	67.13	48.87	169.63	157.38	72.81	65
St. dev.	11.13	31.67	7.16	34.205	11.25	27.84
CV (%)	16.58	64.81	4.22	21.73	15.45	42.83
Median	67.13	56	170	172	73	73
Min	59	2	157	84	55	12
Max	75	87	184	183	90	93

Almost all patients described associated diseases (mostly cardiovascular - 44.29% cases and infections - 34.29% cases) (fig. 2).

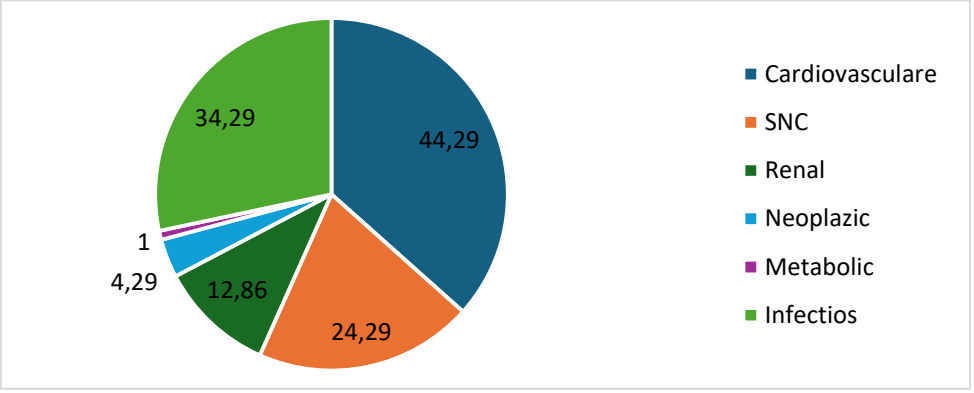

Fig. 2. Comorbidities in patients with HEV CNS infections

Fever was noted in almost all patients with CNS infections (71.43% cases of meningitis *vs.* 56.67% cases of meningitis). Various neurological symptoms were noted in both HEV CNS infections and neck stiffness was identified in both encephalitis and meningitis (fig. 3).

Mean ± standard deviation (CV%) of blood neutrophils to lymphocytes ratio (NLR) was 7.97 ± 3.86 (48.80%) in case of encephalitis, statistically significantly lower than the mean NLR of 12.42 ± 4.12 (33.16%) in case of meningitis (p = 0.04). On other side, NLR in CSF was not statistically different in case of encephalitis and meningitis (0.37 ± 0.28 *vs.* 0.54 ± 0.63, p =0.18) (tab. II).

Although the cellularity in the CSF was not significantly different between HEV encephalitis and meningitis, the biochemical analysis highlighted relevant changes. The level of proteins in CSF was significantly higher in case of meningitis (median of 66 g/l) than in encephalitis (median 1.67 g/l), without significant changes regarding levels of glucose and chloride in CSF.

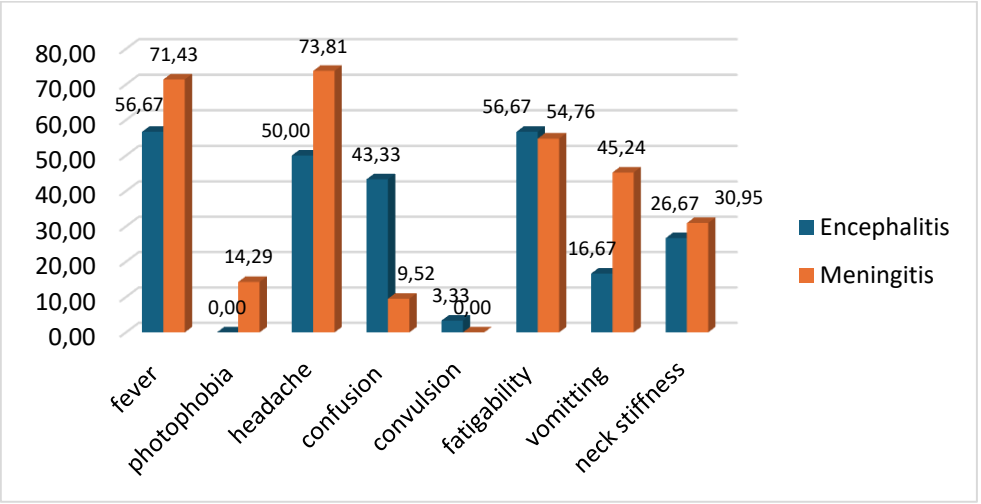

Fig. 3. Symptoms in patients with HEV CNS infections

Max	2.10	164.00	7.69	1.4	87	69.6
P	**0.001**		**0.097**		**0.170**	

The mean duration of hospitalization was 15.63 days (range 2 - 34 days) in case of encephalitis and 10.92 days (range 6 - 27) days in case of meningitis. All patients received antibiotic treatment (third generation of cephalosporins, carbapenems, van-

co-mycin). There were recorded 23.33% cases of death, all being noted in old, immunosuppressed patients (diabetic patients) with HEV encephalitis. There were not noted cases of death in HEV meningitis.

DISCUSSION

We evaluated the clinical - biological features, risk factors and outcomes in HEV meningitis and HEV encephalitis. Sixty - four eligible patients were analyzed. The number of cases of meningitis was slightly higher than encephalitis (57.81% *vs.* 42.18%). All categories of ages were affected, with a wild range in case of meningitis (2 - 87 years).

Fever and headache were the main symptoms noted in both encephalitis and meningitis. Even neck stiffness is a specific feature for meningitis, it was noted also in almost 27% cases of HEV encephalitis. On other side, convulsions were noted in only one case of encephalitis. The clinical profile of HEV infections was similar with other published studies (6, 9, 10).

Neutrophils - lymphocytes ratio (NLR) is a biomarker which is very easy to be calculated and offers important prognosis for various disorders. It is calculated as ratio between counts of neutrophils and lymphocytes measured in peripheral blood. Elevated NLR was associated with bacterial or fungal infections, brain abscesses, stroke, myocardial infarction, serious trauma and is a predictor for efficiency of pharmacological treatment in different conditions (such as lymphoma) (11-13). NLR is also a predictive factor in different types of infections, such as sepsis, pneumonia or bacterial meningitis (14). We have identified in our analysis a significantly elevated NLR in case of HEV encephalitis compared with meningitis. NLR value was also elevated in cases of death. However, significance could not be established due to the low number of cases analyzed.

The value of NLR measured in CSF was not statistically different in both enteroviral CNS infections (meningitis and encephalitis). Nugrahanto *et al.* (2024) demonstrated that the value of NLR is significantly increased in case of bacterial meningitis and combined with the value of serum C reactive protein is an important factor for early detection and prognosis in bacterial meningitis. Our study revealed that NLR could be a marker for diagnosis of encephalitis, but this result will be further evaluated in a larger sample sized study (15).

HEV is mostly responsible for subclinical self - limited infections and is identified in almost 1% cases of viral encephalitis. Mortality is elevated in various conditions (agammaglobulinemia, immunosuppressive therapy) or severe systemic diseases (16).

We noted a high rate of use of antibacterial even after a non-bacterial etiology was confirmed. In line with other studies with similar results, the potential of drug toxicity and development of increased antimicrobial resistance is elevated after use of extended spectrum antibiotics in such cases (17).

The small sample size evaluated is the main limitation of the current study. However, this is an interim analysis of patients hospitalized in our clinic between 2018 - 2019. The number of patients was significantly limited by the years of COVID-19 pandemic when the Clinical Hospital of Infectious Diseases was a first - line hospital addressed only for patients with SARS - CoV2 infections. Further evaluations will be performed on eligible patients to obtain more reliable data.

CONCLUSIONS

Human enterovirus central nervous system infections, mainly encephalitis, are an important cause of mortality in patients with risk factors (elderly, immunosuppres-

sion). Measurement of neutrophils - lymphocytes ratio could be a useful early diagnostic tool for differentiation between meningitis and encephalitis to ensure proper pharmacological management of these pathological conditions.

THE INTERPLAY BETWEEN GASTROINTESTINAL SYMPTOMS AND NUTRITIONAL STATUS IN SYSTEMIC SCLEROSIS PATIENTS (Abstract): Systemic sclerosis (SSc) is a chronic autoimmune disease frequently associated with gastrointestinal (GIT) involvement and malnutrition, which can worsen disease outcomes and quality of life. This study **aimed** to assess digestive involvement and the prevalence of malnutrition in a group of SSc patients and to evaluate the relationship between malnutrition, symptom burden, and disease activity. **Materials and methods:** We included 65 patients with SSc. The UCLA GIT 2.0 questionnaire measured the digestive symptom burden. Malnutrition risk was assessed using the Malnutrition Universal Screening Tool (MUST) and Mini Nutritional Assessment (MNA) scores. We analyzed correlations between malnutrition status, disease activity (EUSTAR-AI index), and digestive symptom burden measured by UCLA GIT 2.0 score. **Results:** Almost 70% of the subjects showed digestive involvement. The prevalence of malnutrition (MNA) was 6.6%, and the risk of malnutrition was 7.7% (MUST). Malnourished individuals experienced significantly higher scores in UCLA (p=0.009), UCLA reflux (p=0.05), UCLA emotional well-being (p=0.001), and UCLA social function (p=0.08), as well as increased disease activity scores (EUSTAR-AI—p=0.027). **Conclusions:** Digestive involvement and malnutrition are frequent among SSc patients, particularly those with higher disease activity scores and GIT involvement. These results highlight the need for rapid gastrointestinal and nutritional management in SSc to improve patient outcomes and quality of life. **Keywords:** SYSTEMIC SCLEROSIS, GASTROINTESTINAL, MALNUTRITION.

INTRODUCTION

Systemic sclerosis (SSc) is a systemic autoimmune disease, with a complex pathogenesis, characterized by skin fibrosis, vasculopathy and internal organs malfunction. The most common symptoms are Raynaud's phenomenon and skin fibrosis (1,2). There are two main subsets of the disease (the limited cutaneous form – lcSSc and the diffuse cutaneous form – dcSSc) that have different developments but also share many characteristics (3). DcSSc is characterized by an early and accelerated organ involvement, a severe prognosis and the presence of anti-Scl 70 antibodies (also known as anti topoisomerase1 antibodies). LcSSc is expressed by a gradual disease development, later

visceral involvement, anti-centromere antibodies positivity, and a better disease prognosis (1,4,5).

After skin, the gastrointestinal tract (GIT) is the second most frequently affected organ. Digestive involvement is observed in 90% of the patients, secondary to progressive fibrosis of the GIT, spanning from the oral cavity to the anus (2,6). This determines the dysmotility and hypomotility of the esophagus, the small intestine, and the gut (7). The GIT involvement causes serious morbidity and affects the survival of these patients (8). The digestive manifestations of SSc may vary depending on the affected area of the GIT (8,9,10). Esophageal symptoms are reported by up to 90% of patients (4). In general, patients experience mild gastroesophageal reflux disease. However, severe dysmotility of the upper and/or lower bowel can also be present in some cases, causing severe manifestations. For example, almost half of the patients experience gastric dysfunction characterized mainly by gastroparesis and gastric antral vascular ectasia (GAVE) (2,11). Dysmotility of the small bowel occurs in up to 80% of the subjects, with the small intestine being considered the second most affected digestive organ (2,12). As far as the colon is concerned, in up to 50% of the patients varying bowel patterns may be observed, alternately constipation and diarrhea or other symptoms such as bloating, distention, malnutrition or bleeding (13,14).

The GIT can be involved in both forms of SSc, although it can be more frequent or more severe in the diffuse phenotype. Other risk factors for severe GIT involvement include male sex, myopathy, and sicca symptoms (15). The severity of digestive symptoms is also associated with emotional distress and depressive disorders (16,17).

It is not entirely understood how the SSc-GIT symptoms develop over time and despite the significant prevalence of GIT disease in SSc, there are few available treatments (18). Severe digestive involvement can lead in time to malnutrition.

In SSc, malnutrition is reported as an independent risk factor for mortality, being associated with cardiac and gastrointestinal involvement, inflammatory status, dysphagia, and chronic intestinal pseudo obstruction (19,20). Malnutrition results from GIT involvement but also intensifies the illness, creating a vicious cycle of deteriorating nutritional status and exacerbating systemic symptoms.

Depending on the assessing methods used for defining the risk of malnutrition, its prevalence in SSc ranges between 18% and 38% (21,20). For example, when using the MUST score, in a Canadian cohort of 586 SSc patients, 10.8% were at medium risk for malnutrition and 17.4% were at high risk. When compared to MUST score for hospitalized patients, the results were similar (21). Higher prevalence of malnutrition were obtained by a French study group that defined malnutrition as one of the following three options: weight loss of > 5% over one month or more than 10% over 6 months, BMI < 21 kg/m^2, or albuminemia < 35 g/L. In their cohort, 38.3% were at high risk according to MUST, 59.2% of the patients were diagnosed with malnutrition, and 25% had severe malnutrition (20).

There are various screening tools for malnutrition and the ESPEN recommends using Nutritional Risk Screening 2002 (NRS – 2002) for patients in the hospital, MUST (The Malnutrition Universal Screening Tool) in the community, and the first part of MNA (Mini Nutritional Assessment) for elders (22).

To assess the digestive involvement in SSc, clinicians can use the University of California at Los Angeles Scleroderma Clin-

ical Trial Consortium GIT 2.0 (UCLA SCTC GIT 2.0) instrument. Although objective studies are the gold standard for diagnosis of GIT involvement, UCLA SCTC GIT 2.0 reflux and distention/bloating scales are sensitive enough and complement the objective methods (23). It is a validated questionnaire, completed by the patient that evaluates seven domains covering a variety of digestive symptoms. It can also highlight the need for further investigations of the GIT, being a useful tool in the screening of SSc patients (24).

It can be very difficult to identify individuals who are at a high risk of experiencing clinically substantial weight loss or malnutrition because GIT symptoms are frequent in SSc patients. In this context, we aimed to explore the range of gastrointestinal symptoms in patients with SSc and evaluate if there are any correlations with the risk of malnutrition.

MATERIALS AND METHODS

We performed an observational study in which we included 65 patients with a SSc diagnosis according to the American College of Rheumatology/European League Against Rheumatism (EULAR) 2013 classification criteria for SSc. The patients were adults admitted to the rheumatology department for revaluation. Patients with mixed connective tissue disease, overlap syndrome, neoplasia, or who refused to participate were excluded.

Information about age, sex, use of immune modulatory treatment, the type of SSc according to LeRoy criteria (25), and other clinically relevant data for our study were taken from the medical records. The modified Rodnan skin score (mRSS) was used for skin involvement assessment. Using venous blood samples, we performed within the hospital laboratory a biochemical evaluation. The hospital laboratory also measured the serum antinuclear antibodies, anti-topoisomerase I, and anticentromere antibody titers. Esophageal reflux presence was considered if patients complained about heartburn or regurgitation. The disease activity was evaluated using the EUSTAR-AI tool (European Scleroderma Trials and Research group Activity Index). Active disease was defined as having an EUSTAR-AI score exceeding 2.5.

We also evaluated the following anthropometric parameters: height (H), weight (W), and body mass index (BMI, calculated as W/H^2). Using the World Health Organization definition for BMI classes our subjects were divided into underweight (BMI under 18.5 kg/m^2), eutrophic (BMI between 18.5 and 24.9 kg/m^2), pre-obesity (BMI between 25.0 and 29.9 kg/m^2) and obesity (BMI greater than 30 kg/m^2).

To evaluate the digestive involvement we used a translated, adapted, and validated version of the UCLA GIT 2.0 questionnaire (26). The questionnaire included 7 categories of symptoms: reflux, distention/bloating, fecal continence, diarrhea, constipation, social function, and emotional well-being. The final score is the average of the scores for each category (except constipation) and may vary between 0 and 2.83. We defined the presence of gastrointestinal involvement if the patients had a total score or at least one of the seven categories > 0. The score was interpreted as previously described by van Leeuwen et al. (27). It was divided into none-mild (a score of 0 or < 0.5), moderate (a score ≥ 0.5 but less than 1.01), and severe (≥ 1.01). For fecal incontinence and distention/bloating items, the symptoms were considered none-mild for a score < 1.01, moderate ≤ 1.61 for distention/bloating and ≤ 2.01 for fecal soiling, and severe if the score was > 1.61 for distention/bloating and > 2.01 for fecal soiling.

The risk of malnutrition was evaluated using the translated version of MNA (Mini Nutritional Assessment) score where malnutrition was defined with a score less than or equal to 7, risk of malnutrition with scores between 8 and 11, and normal nutrition with values greater than 11. We also performed the MUST score and patients were classified as being at low risk (MUST score = 0), at moderate risk (MUST score = 1) or at high risk of malnutrition (MUST score ≥ 2).

The Ethics Research Committee of the Clinical Rehabilitation Hospital from Iasi and the University of Medicine and Pharmacy "Grigore T. Popa" Iasi approved the study and ensured compliance with the principles of the Declaration of Helsinki. Subjects gave written informed consent to undergo the examination.

For the statistical analysis, the tests were performed on SPSS version 26. Categorical variables were presented as proportions and Fisher's test was performed. Continuous variables were expressed as mean and standard deviation. Statistically significant differences between patients with lcSSc and dcSSc were assessed by independent *t* test.

RESULTS

General characteristics. A number of 65 patients with SSc met the inclusion criteria and completed the questionnaires. According to the LeRoy classification criteria, 27 had a limited form of SSc, and 38 had a diffuse subset. The majority were women (86.2%) with a mean age of 57.15 (±10.35) years old. The mean disease duration was 8.48 (±7.09) years. Anticentromere antibodies were present in 38.5% of the patients, while 49.2% of the subjects were positive for anti-SCL70 antibodies.

The demographic and other clinical data are displayed in the first table. The results are expressed as mean ± standard deviation for continuous variables and as number (percentage) for categorical variables. Inflammatory syndrome was considered if either ESR or CRP were elevated. mRSS – modified Rodnan skin score; BMI – body mass index; ILD – interstitial lung disease.

Inflammatory syndrome, described as the presence of ESR (erythrocyte sedimentation rate) and CRP (C reactive protein) above the laboratory normal values, was identified in 52.3% of the patients, more than half of whom had dcSSc.

Interstitial lung disease (ILD) was reported in 63.1% of the patients, mainly in dcSSc subjects (73.7%, *p=0.04)*. Patients with ILD had more often SCL70 antibodies (*p= 0.01)*, higher mRSS skin scores (*p=0.002),* and higher values for muscular enzymes (creatine kinase – *p=0.04* and lactate dehydrogenase – *p=0.014*).

Digestive involvement

Digestive involvement was considered in patients who exhibited gastrointestinal tract symptoms and was present in nearly 70% of those included. Dysphagia was reported in 53.8% of the patients, slightly more frequent in the dcSSc type (55% vs 51%). Early satiety was present in 49.2% of the subjects, of which 63% had lcSSc (*p=0.08)*. Esophageal reflux was spotted in 76.9% of the subjects, with no difference between the two subsets of the SSc. Patients with reflux also had lower interincisive distance (p= 0.05), lower weight, higher CRP levels, and higher EUSTAR-AI scores– with no statistical significance.

Significant differences according to t test for continuous variables and Fisher's exact test for categorical variables comparing lcSSc to dcSSc are highlighted by p values.

The overall UCLA GIT 2.0 score was similar between the two phenotypes of SSc, with the majority of the patients describing none to mild symptoms. Patients with

dcSSc were more likely to have reflux, but the results did not reach statistical significance (0.79 vs 0.69). Furthermore, the reflux symptoms were more serious in dcSSc patients, as 13 vs 5 patients experienced severe UCLA GIT 2.0 scores. UCLA constipation score was higher in lcSSc patients compared to dcSSc patients (0.59 vs 0.36, *p=0.08*) but the difference did not reach statistical significance. Regarding the other domains of the UCLA SCTC 2.0 tool, the scores were similar between the two groups of lcSSc and dcSSc, most of the patients describing none to mild symptoms in all of the categories (tab. II).

Patients with extensive cutaneous involvement, according to mRSS score, had higher UCLA reflux scores (*p=0.07)*.

Anticentromere positivity correlated with higher scores for UCLA (*p=0.048)*, UCLA social function (*p=0.049*), UCLA emotional well-being (*p=0.036),* and UCLA constipation (*p=0.003)*. Furthermore, anticentromere antibodies correlated with moderate digestive involvement according to UCLA severity (*p=0.012)*.

TABLE I.

Characteristics of the study subjects.

General characteristics	Overall (n=65)	lcSSc (n=27)	dcSSc (n=38)	*p*
Age	57.15 ± 10.35	60.44 ± 8.11	54.82 ± 11.20	0.02
Gender, n (%female)	86.2%	100%	76.3%	0.008
Disease duration	8.48 ± 7.09	11.41 ± 7.9	6.39 ± 5.6	0.007

Severe, n (% total)	11 (16.9%)	3 (11.1%)	8 (21.1%)	
UCLA constipation	0.457 (0.535)	0.592 (0.524)	0.361 (0.528)	0.08
None-Mild n (%total)	34 (52.3%)	11 (40.7 %)	23 (60.5 %)	
Moderate, n(%total)	24 (36.9 %)	11 (40.7 %)	13 (34.2 %)	0.054
Severe, n (% total)	7 (10.8 %)	5 (18.5 %)	2 (5.3 %)	

Malnutrition. According to MUST, the risk of malnutrition was high in 7.7% of the patients, moderate in 10.8%, and low in 66.2%. Subjects with a high risk had lower interincisive distance (p=0.03) and higher scores in almost all of the UCLA domains except constipation, but the results did not reach statistical significance.

Based on the MNA, malnourished individuals (6.2% of the subjects) experienced higher values for UCLA (*p= 0.009)*, UCLA reflux (*p=0.05)*, UCLA emotional well-being (*p= 0.001)*, and UCLA social function (*p=0.08)*. Malnourished patients also had higher disease activity scores calculated with the EUSTAR-AI index (*p= 0.027)*. MNA evaluation score also correlated with the presence of dysphagia (*p=0.05)*.

DISCUSSION

In current literature, GIT involvement is present in nearly all SSc patients at various

extents (28). According to the 2012 EUSTAR cohort, gastroesophageal symptoms are the most common, reported in more than 60% of the patients (29). GERD symptoms are more frequently reported (in almost 80% of the cases) if ILD is associated (30). In very early SSc, severe GIT involvement can be present in 15% of the cases, being associated with telangiectasias, higher skin scores, inflammatory myositis, but also with high mortality and low quality of life (31). Severe gastrointestinal involvement can initially lead to unintentional weight loss, which may become significant and result in malnutrition. Male sex, dcSSc, digital ulcers, shorter disease duration, elevated erythrocyte sedimentation rate (ESR)/C-reactive protein, elevated creatine kinase (CK), pulmonary hypertension, aberrant diastolic dysfunction, and interstitial lung disease were among the clinical characteristics linked to significant weight loss (32).

Using the UCLA SCTC GIT 2.0 tool, the severity of the GIT symptoms varies from absent to very mild in 39% of the patients, to mild in 21% of the patients, moderate in 31%, and severe to very severe in 9% of the patients (24). A more recent study that included 834 SSc patients, which used the UCLA SCTC GIT 2.0 questionnaire to evaluate the digestive symptoms, reported none to mild in 73% of the subjects, moderate in 21%, and severe in 7% of the subjects. The same study declared that female sex, smoker status, presence of anticentromere antibodies, and corticosteroid usage were associated with more severe GIT involvement (27).

In the present study, we report that nearly 70% of the patients with SSc experience digestive symptoms, especially gastroesophageal reflux. Alastal *et al*. reported a frequency of 59.24 % for digestive involvement, and GERD was present in 34.8% of the subjects included (33).

The severity of digestive symptoms correlated with the presence of anticentromere antibodies, as these patients reported higher scores for nearly all UCLA domains. These results align with those previously described in the literature (27).

MUST and MNA scores focus slightly differently depending on the questions included: MUST focus more on BMI, recent weight loss, and acute disease, while MNA includes questions on dietary intake, mobility, and psychological stress. According to MNA, 6.2% of the patients in our study group were malnourished. Cano Garcia *et al*. reported lower malnutrition rates using the same index and correlated the results with diffuse skin involvement and sarcopenia (34). According to MUST, 7.7 % of our study group were at high risk of becoming malnourished. We obtained lower rates of malnutrition in our study compared to the existing literature (20,21).

Malnutrition exacerbates GIT symptoms, resulting in a vicious cycle of worsening systemic symptoms and declining nutritional status. Caimmi *et al*. (35) have previously demonstrated that MUST scores correlate with UCLA GIT values. In our case, we obtained higher UCLA scores in malnourished patients, suggesting that digestive involvement impacts their food intake, emotional well-being, and social functioning.

Furthermore, we observed a connection between malnutrition and disease severity measured with the EUSTAR-AI index. A more active disease often involves systemic inflammation, which can increase metabolic demands and reduce nutrient absorption. In our study group, malnutrition seems to be both a consequence of high disease burden and GIT involvement but also a factor that may intensify symptom severity.

The current investigation is constrained by a limited sample size of enrolled pa-

tients. Another limitation is that UCLA GIT is a self-reported questionnaire designed to assess symptoms in the past seven days, potentially introducing bias. Patients with GIT symptoms were not further evaluated with objective measurements to confirm the digestive pathology.

CONCLUSIONS

In conclusion, our data gives information about the high frequency of GIT symptoms in patients with SSc. The assessment of digestive involvement using the UCLA SCTC GIT 2.0 questionnaire provides a systematic approach to characterize the spectrum of GIT manifestations. It facilitates early detection of GIT symptoms and their impact on patient's quality of life, enabling clinicians to further recommend objective methods for the diagnosis of GI disease. Digestive involvement in systemic sclerosis patients often leads to nutritional impairment. Malnutrition can worsen the severity of SSc, creating a cycle where increased disease activity and symptom burden further deteriorate nutritional status.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

SPATIAL-TEMPORAL PATTERNS OF DIABETES PREVALENCE IN ROMANIAN COUNTIES BETWEEN 2012-2021: INSIGHTS FROM THE COMPARATIVE ANALYSIS OF TIME SERIES (Abstract): Our study investigates the evolution of Diabetes prevalence in Romania across a 10-year period (2012-2021) by applying comparative time series analysis techniques to epidemiological data recorded from all 41 counties of Romania, as well as Bucharest. **Materials and methods**: The main goal was to highlight the similarities and differences between counties, through several methods: the distance-based analysis of the observed values (Euclidean distances) and trends (Manhattan distance), followed by the study of correlations between the standardized Z-scores of the original values and the counties Hierarchical Clustering. **Results:** Our findings revealed significant geographical similarities, confirmed simultaneously by two or more methods among the four involved. These results are exemplified with the particular case of Iasi county, which was found as having a similar behavior with Arges, Dolj and Bihor counties according to the previously stated condition; the in-depth analysis of socio-demographic features explains the detected similarities. **Conclusions:** The study highlights the added value of time series analysis over classical cross-sectional approaches, as it enables the detection of more complex relationships between the raw epidemiological data, expressed through trends, statistical anomalies, or regional clusters. Such results have direct implications in optimizing the public health policy, particularly required in chronic diseases like diabetes**.** **Keywords:** TIME SERIES ANALYSIS; DIABETES MELLITUS; TREND ANALYSIS; EPIDEMIOLOGY.

INTRODUCTION

Time series analysis is of great interest in medical studies, as numerous clinical, epidemiological, and public health phenomena manifest and evolve over time. Time series enable the monitoring of disease incidence and prevalence, highlighting the trends and the possible seasonal components, thus providing a solid foundation for forecasting future cases. The statistical tools used to investigate and quantify the evolution of time series are highly versatile, being primarily focused on their description and modelling in order to detect patterns. This facilitates a better understanding of the phenomenon dynamics over

time and supports the development of more accurate forecasts (1).

The behavior of a time series (2) is quantified through four components: trend (T), representing the general long-term direction; seasonality (S), corresponding to regular short-term fluctuations; cyclicity (C), reflecting irregular long-term variations; and residuals (R), which account for random variations. Time series are described by combining these using two approaches: additive models ($Y = T + S + R$) or multiplicative models ($Y = T \times S \times R$).

The main statistical techniques for analysis aim to characterize the observed behavior by identifying autocorrelations and making forecasts. The autocorrelations assess the dependence degree between the values of the series at different points in time, highlighting therefore the possible patterns. The forecasting extrapolates the series' behavior into the future using well-defined mathematical models: autoregressive models (AR), which estimate future values based on past values; moving average models (MA), which rely on past errors; ARMA or ARIMA models, which combine the previous two and may also include a seasonal component (SARIMA); and Exponential Smoothing models, which account for both trend and seasonality (3, 4, 5). The major challenge lies in identifying the optimal model, which is typically achieved through successive testing of all possible alternatives.

A particular aspect of this analysis is the comparative study of multiple time series (6), aimed at identifying similarities between them and understanding their temporal evolution in order to determine whether phenomena observed in different contexts follow similar or divergent dynamics. The comparative study of time series investigates separately each one of the elements that characterize them. It typically begins with the comparison of absolute values, followed by trend comparison, analysis of shape similarity (through correlations and distance functions), clustering based on their temporal trajectories, and, if applicable, identification of causal or synchronized relationships through cross-correlations (7, 8).

These investigation techniques hold particular importance in the medical field, as they allow to detect common patterns among areas or patients' samples, facilitating further to depict the significant determinants (behavioral, environmental, or the result of certain health policies). Consequently, areas exhibiting similar trends can benefit from coordinated prevention and treatment measures, which optimizes the transfer of best practices and the alignment of public health interventions, improving also their effectiveness and impact in real-time.

A relevant example in this regard is the comparative study of the incidence and prevalence of various pathologies across geographically or administratively distinct areas, aiming to highlight the degree of similarity or divergence between them. Such information becomes the starting point for further analyses regarding potential causes, consequences, and recommended intervention strategies. This is the objective of the present study, in which we propose a reinterpretation, from a new perspective, of data regarding the prevalence of diabetes cases in all counties of Romania over a 10-year period (2012-2021). We approached these data from a global perspective, aiming to compare the regional evolution of this pathology, in order to identify similarities and differences and to provide therefore a reliable basis for well-informed medical decisions and, consequently, for more accurately tar-

geted interventions.

MATERIALS AND METHODS

Database. The database used in our analysis was extracted from a report achieved by the National Institute of Public Health in 2022, regarding the Diabetes Evolution Evidence in Romania, between 2012-2021 (insp.gov.ro). Other newer public data regarding the Diabetes incidence and prevalence in Romania between 2022-2025 were unavailable - that is why we limited our analysis to these data. However, this does not jeopardize the quality of the analysis we intended to carry out, as the territorial similarities we aimed to highlight are not significantly affected by the novelty of the data, depending primarily on the investigated time series accuracy and length.

Methods. The transversal analysis of multiple time series is a sort of statistical comparison between them, conducted in order to identify the existent similarities regarding the direct values, as well as the evolution trends, patterns and periodicity (if any).

The initial approach consists in the visual inspection of the observed values, typically conducted through standard distribution charts. A good practice is to standardize the values, by calculating the corresponding Z-scores - because in this way we eliminate the influence of absolute values, being able to focus better on the trend. The distribution charts usually highlight the general behavior, as well as the trend's direction and the possible points of inflexion.

It follows the analysis of differences between paired values (by noticing how many of them are positive and how many are negative) and of ratios between them (by noticing how many are much higher above 1). A more accurate approach is instead to calculate a distance function between values (9); usually an L-p distance function is recommended, $(x, y) = (\sum |x_i - y_i|^p)^{\frac{1}{p}}$, the most efficient in such cases being the L-2 distance (the Euclidean norm), $D(x, y) = (\sum |x_i - y_i|^2)^{\frac{1}{2}}$ (10). This distance is particularly very popular because it has the properties to be preserved under orthonormal transformations (it is the only one with this property among the class of L-p norms) and to be optimal for estimation in the presence of Gaussian additive noise. Other distance measures recommended in such situations are the Manhattan distance, $D(x, y) = \sum |x_i - y_i|$ and the infinite norm distance, $D(x, y) = \max |x_i - y_i|$ (11). In our study, due to the exposed reasons, we conducted the analysis based on the Euclidean norm.

The final purpose of this analysis is in fact to identify the so-called "significant" similarities between counties; unfortunately, the scientific literature does not provide an appropriate significance test. Therefore, our solution was to calculate the range of Euclidean distances between counties and to report as significant the distances smaller than the 5th percentile, as well as the distances between the 5th and the 10th percentile within this range. Heatmaps and 3D surface charts are the best methods to represent intuitively such results, as well as the tables with similarities.

The next step is to compare the time series evolution, reflected by their trends, patterns or periodicities (12, 13). The easiest way to calculate the trends is through linear regression models; the trend is actually the slope of the regression line between x = the year (between 1 - 2012 and 10 - 2021) and y = the yearly number of new cases for each monitored county. In order to depict the similarities between trends, the available solution is to calculate

again the differences between them, using dedicated measures; we used the Manhattan distance in this regard. The significant similarities between trends were identified also through range analysis - the distances smaller than the 5th percentile and the distances between the 5th and the 10th percentile within the range were reported as significant.

Another available method to depict similarities between trends is based on the Z-scores of the original values (14); since such scores have the property to remove the noise and to preserve the trend, the calculation of correlation coefficients between them is able to provide the significant similarities - they correspond to significant correlation coefficients, bigger than 0.7.

A third method in the same regard is the Z-scores Hierarchical Clustering, based on Ward's method and the Euclidean distance - this is a powerful tool to highlight the time series with similar evolutions (15, 16). Ward's method is an appropriate choice because it minimizes the interval variation of each cluster, in order to create clusters of counties which are similar between them and as different as possible from the others.

We used all these methods on our data, in order to compare their performances in identifying similarities between Romanian counties in which concerns the evolution of Diabetes cases between 2012-2021.

The calculations were made in *SPSS 29.0, MATLAB 2010* and *Microsoft Excel.*

RESULTS

The analysis was carried out on 43 time series (corresponding to the 41 counties of Romania, as well as to the Bucharest area and the whole country).

In the first step of our analysis we proceeded with the direct investigation of the recorded values, represented through distribution charts (fig. 1, 2).

We created the distribution charts for the original values (fig. 1), as well as for the corresponding Z-scores (fig. 2).

Due to the chart's complexity (the increased number of lines) it is rather difficult to analyze them and to compare the cases evolution in different counties; anyway, the Z-scores chart emphasizes clearly that we are dealing in all cases with ascendant trends.

In the next step of our analysis we calculated the Euclidean distances between all possible paired values, in order to identify the similarities between counties, according to the proposed criteria of significance, based on percentiles. The chart of Euclidean distances between counties in which concerns the yearly number of Diabetes cases is presented in third figure.

The range of variation is 431700.93, the minimal Euclidean distance being equal with 1740.46 and the maximal one being equal with 433441.39. As we already stated, we divided the total range of variation in 11 intervals, defined by the percentiles 0.05, 0.1, 0.2 … 0.9 and we grouped the pairs of counties falling within each interval of variation (tab. I).

The next step of the study was the investigation of the recorded time series trends, by analysing first the differences between slopes, calculated using the Manhattan distances. The chart of Manhattan distances between trends is presented in fourth figure.

The range of variation is 7985.60, the minimal Manhattan distance being equal with 0.66 and the maximal one being equal with 7985.60. We divided again the total range of variation in 11 intervals, defined by the percentiles 0.05, 0.1, 0.2 … 0.9 and we grouped the pairs of counties falling within each interval of variation (tab. II).

Percentile 0.8 - 0.9	68035.68 - 90569.12	BN - AG / BH; BV - BN; BR - AG / BH; CL - AG / BH / BV; CJ - BN / CL; CT - BN / BT / BR; CV - AG / BH / BV / CJ; DJ - AB / BT / CS; GR - AG / BV / CJ; GJ - CT / DJ; HR - AG / BH / BV / CT; HD - CV / GR; IL - AG / BH / BV / CJ; IS - BN / BR / CL / CV / HR / IL; IF - CT / DJ; MH - AG / BH / BV / CJ / HD / IS; OT - DJ; PH - AB / BT / BR / CS / GJ / HR / IF / OT; SM - DJ; SJ - CT / PH; SV - GR; TL - DJ / PH; TM - AR / BC / BZ / DB / GL / MM / MS / NT / SM / SB; TL - AG / BH / BV / CJ / IS; VS - DJ / TM; VL - DJ; VN - BH / CT / IS / PH.
Percentile 0.9 - 1	90569.13 - 433441.39	CT - CL; CV - CT; DJ - BN / BR / CL / CV; GR - BH / CT / DJ; HR - DJ; IL - CT / DJ; IS - GR; MH - CT / DJ; PH - BN / CL / CV / GR / IL / MH; SJ - DJ; TM - AB / BN / BT / BR / CS / CL / CV / GR / GJ / HR / IL / IF / MH / OT / SJ / TR; TL - CT / DJ / PH / TM ; VL - TM; VN - DJ / TM; Bucuresti - all counties.

* the 2-letters abbreviation codes for Romanian counties were used (https://enciclopediaromaniei.ro/wiki/)

It follows therefore that the smallest distances between counties, which belong to the 0.05 percentile and can be characterized as significant, are recorded between BH - AG / IS; BZ - AR / NT / SB / SV; CS - BT / IF / TR; CL - BN / IL / TL; GL - BC; GR - CV; GJ - BT / IF / SJ / VN; HR - BR / SJ / VN; IS - AG; IF - BT / SJ / TR; MM - BC / DB / SM; NT - AR / SB / SV; SM - DB / VS; SJ - BT / VN; SB - AR; SV - AR / HD; TR - BT; TL - CV / IL; VL - VS; VN - BR. It can be noticed, for example, that Iasi county is the most similar with Bihor and Arges counties in which concerns the number of Diabetes cases recorded between 2012-2021.

The smallest distances between trends, which belong also to the 0.05 percentile and can be characterized as significant, are recorded between AB - IL; AR - GJ / MM; BC - CL / HR / SJ / VN; BH - BZ; BN - SJ / VN; BT - SJ; BR - CS / IF / PH / VS / VL; BZ - TM; CS - IF / VS / VL; CL - HR / SJ; CV - TL; DM - HD / **IS** / NT / SB; GL - GR; GJ - MM; HR - SJ / VN; HD - **IS**; **IS** - NT / SB / SV; IF - PH / VS / VL; NT - SB / SV; PH - VL; SB / SV; VS - VL. The analysis reveals that Iasi county has the most similar trends with Dambovita, Hunedoara, Neamt, Sibiu and Suceava counties.

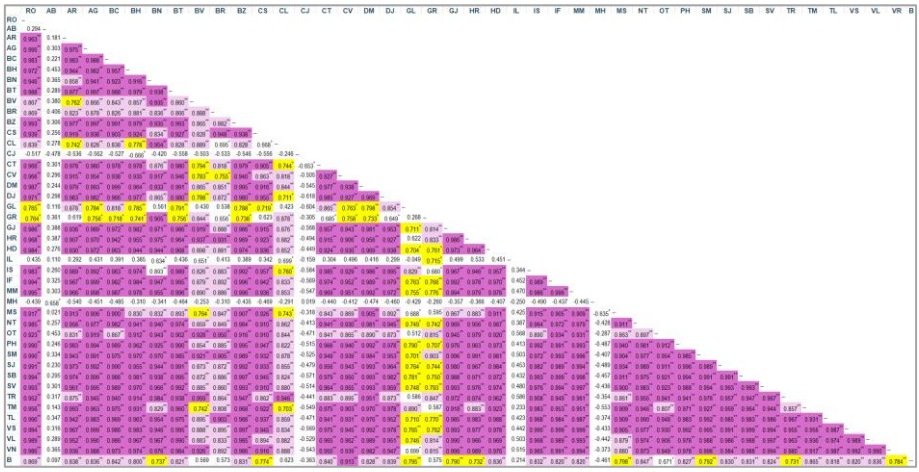

Fig. 5. The correlation matrix between counties
(the Z-scores of the yearly number of Diabetes cases)

We calculated also the correlation coefficients between the Z-scores of the original values, as another method to identify the significant similarities between trends, according to the theory.

The correlations matrix (figure 5) shows strong and significant correlations between almost all counties, including Bucuresti and the whole country. Anyway, there are a few counties not correlated at all (Alba, Cluj, Ialomita and Mehedinti), as well as a few others weaker correlated, even significant - namely Brasov, Braila, Calarasi, Galati and Giurgiu. Iasi county is the strongest correlated with Arges, Buzau and Dolj and the weakest correlated with Bistrita-Nasaud,

Brasov, Braila, Galati and Bucuresti. These results confirm partially the previous ones, but the correlations analysis seems to be less sensitive, because it identifies strong and significant correlations between almost all investigated counties.

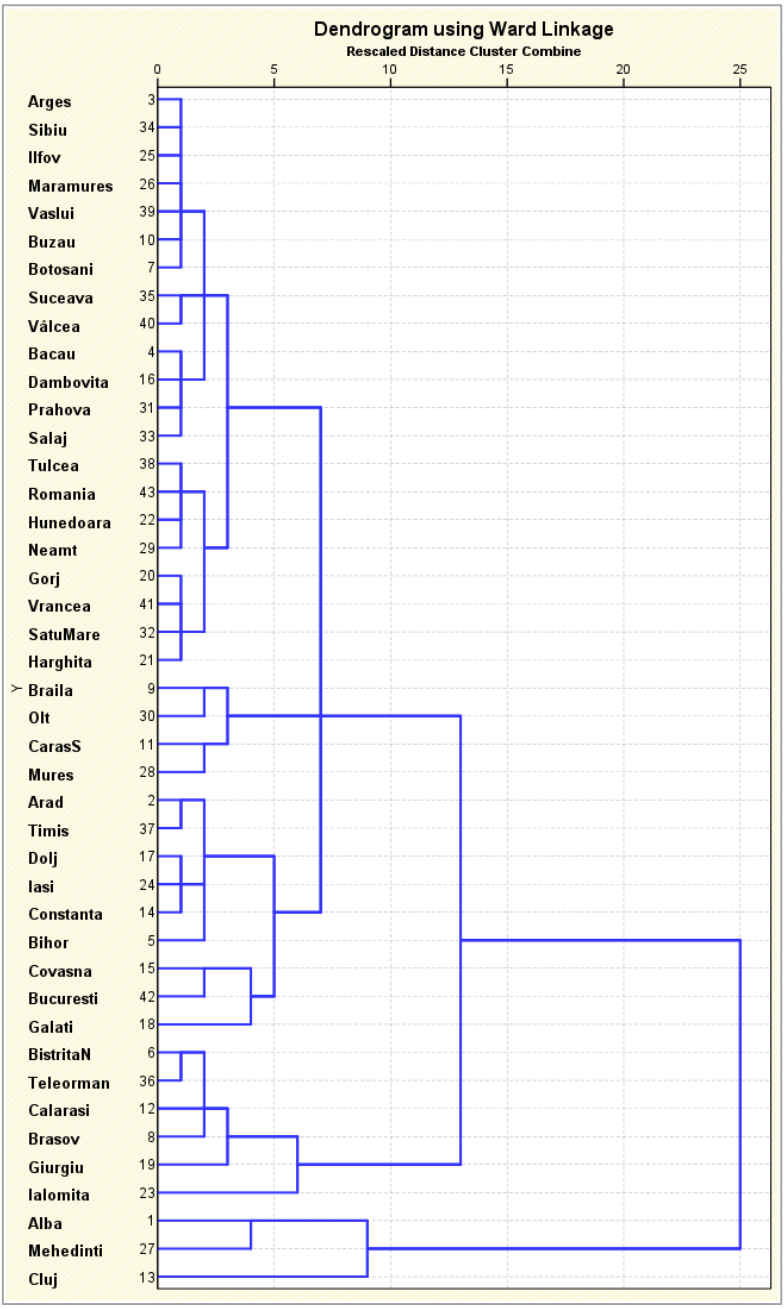

Fig. 6. The dendrogram of the counties according to the hierarchical clustering

Finally, we applied the Hierarchical Clustering of the 41 counties and Bucharest, also in order to identify the similar evolutions. The dendrogram (fig. 6) highlights 5 main clusters, as it follows:

- Cluster 1 - Arges, Sibiu, Ilfov, Maramures, Vaslui, Buzau, Botosani, Suceava, Valcea, Bacau, Dambovita, Prahova, Salaj, Tulcea, Romania, Hunedoara, Neamt, Gorj, Vrancea, Satu Mare, Harghita: these counties are very similar in behavior between them, as well as with the whole country;
- Cluster 2 - Braila, Olt, Caras-Severin and Mures;
- Cluster 3 - Arad, Timis, Dolj, Iasi, Constanta, Bihor, Covasna, Bucuresti and Galati;
- Cluster 4 - Bistrita-Nasaud, Teleorman, Calarasi, Brasov, Giurgiu, Ialomita;
- Cluster 5 - Alba, Mehedinti, Cluj.

DISCUSSION

Each of the presented methods provides slightly different similarity patterns between the counties of Romania regarding the evolution of diabetes cases over the 10-year monitoring period. This is not necessarily surprising, as the working methodologies differ, and the statistical parameters used as reference points also vary. However, the usefulness of employing these tools in parallel lies in identifying potential points of convergence in the results, which indicate significant similarities in the evolution of the time series under investigation.

In the specific case of Iași County, which was used for exemplification, three points of convergence can be observed: Argeș County, which exhibited similarities both in the calculation of Euclidean distances between annual case numbers and in the correlation of trends; Bihor County, identified through both Euclidean distance calculations and hierarchical clustering; and Dolj County, highlighted through the trend's correlation and hierarchical clustering. It can therefore be concluded that the time series of diabetes cases recorded in Iași between 2012 and 2021 shows the highest degree of similarity with the corresponding time series recorded in the aforementioned counties-namely, Argeș, Bihor, and Dolj.

TABLE III.

Socio-demographic indicators relevant for Diabetes prevalence

	Iasi	**Arges**	**Dolj**	**Bihor**
Total population (2025)	988621	606726	663167	608277
% population > 65 y.o. (2024)	17.03%	20.98%	20.87%	18.63%
Average age (2023)	39.0	43.9	43.1	41.4
Population density (/ km^2)	140	83	81	73
Urban (%) / Rural (%)	~50/50	~55/45	~55/45	~60/40
GDP per capita (2022)	12,027 EUR (average)	13,660 EUR (average)	11,898 EUR (average)	12,139 EUR (average)
Average net monthly income (2024)	5,177 RON	4,824 RON	4,750 RON	4,506 RON
County Performance Index (2024)	8	7	5	9
Diabetes: prevalence (%, 2024)	~6.5%	~6.5%	~6.5%	~14.8%
Diabetes: mortality rate (/100000 inhabs 2023)	19.8	59.4	2.3	1.1

(http://cumstam.ro / http://statistici.insse.ro)

It is interesting to discuss about the reasons of these similarities, because, apparently, there are no obvious resemblances between these counties. Iasi belongs to the Moldavia region, while Arges and Dolj belong to Oltenia and Bihor belongs to Transylvania. A more in-depth analysis, however, highlights relevant similarities (tab. III).

Firstly, the topography of the four counties is relatively similar - characterized by hilly and plain areas. Moreover, all four counties have a population of over 600,000 inhabitants, with an urban population share between 50% and 60% and extensive rural areas. Consequently, the population's lifestyle is relatively urbanized, though not highly sophisticated, which leads to common nutritional risks (mainly a hypercaloric diet, characterized by high consumption of processed foods, sweets, and sugary drinks, sedentary behavior, and average access to health education).

All four counties are located in regions with medium levels of economic development - neither extremely poor nor highly affluent - which favors unhealthy dietary habits, primarily represented by a hypercaloric diet and consumption of processed foods, that are tasty but relatively inexpensive. Another relevant aspect is that the population's age structure is relatively aged, which increases the prevalence of chronic diseases, including diabetes.

Each county has at least one medical university center or a county-level reference hospital, ensuring a relatively uniform process of diagnosis, convergence in reporting and monitoring cases, as well as standardization of treatment and prevention protocols. All four counties have equally benefited from national prevention and screening programs implemented through family medicine, resulting in comparable levels of health education. These shared features are significant arguments to support the detected similarities in the prevalence of diagnosed cases during the monitored period.

An interesting aspect - one that requires further analysis - is the evolution observed in 2024: while in Iași, Argeș, and Dolj the prevalence of diabetes remained close to the national average of 6.5%, in Bihor a significant worsening was recorded, reaching 14.8% - more than double the national average. This can be a relevant subject for future researches.

CONCLUSIONS

Therefore, the comparative analysis of time series provides essential insights into the temporal and spatial evolution of diseases' prevalence, offering an approach that integrates the recorded absolute values with trends, disease dynamics, and potential anomalies - such elements cannot be identified through classic cross-sectional studies. Tools such as heatmaps, clustering, and cross-correlation allowed the optimal visualization of inter-county relationships and the identification of geographic areas exhibiting similar epidemiological behavior.

Such information has direct applicability in calibrating better the screening and prevention campaigns, and improve significantly the resources allocation, allowing to tailor optimally the public health policies to the specific context of each county. This spatial-temporal integrative approach is crucial to put in practice the concept of

evidence-based medicine, especially in the case of chronic diseases with slow progression, multifactorial causes, and major impact on the healthcare system such as Diabetes Mellitus.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

PROGNOSIS OF POSTOPERATIVE LUMBAR DISCITIS FOLLOWING LUMBAR DISC HERNIATION SURGERY: AN ANALYSIS OF RISK FACTORS (Abstract): Postoperative lumbar osteodiscitis is a rare but serious complication following spinal disc surgery, with a prevalence of 3-5% of cases. It is commonly caused by septic or aseptic factors, and early diagnosis is essential for effective management. The study **aims** to evaluate the risk factors associated with the development of osteodiscitis following lumbar disc herniation surgery, particularly focusing on lifestyle-related factors and comorbidities. **Materials and methods:** A retrospective, cross-sectional study was conducted between 2018 and 2024, analyzing clinical observation records from two hospitals in Bucharest. The study included 85 patients who developed postoperative lumbar osteodiscitis. Patient data, including risk factors such as smoking, alcohol consumption, poor hygiene, and comorbidities, were collected and analyzed. The association between these factors and the duration of symptom onset, as well as the impact on postoperative pain scores (VAS), was examined. **Results:** The study found that lifestyle-related factors, particularly smoking, were prevalent in 27 out of 85 patients. The mean duration until the onset of symptoms was not significantly influenced by these factors. Patients with comorbidities were typically older, with a significant difference in mean age between those with and without comorbidities. A reduction in VAS scores was observed post-treatment for all patients, although no statistically significant differences were found in pre- and post-treatment VAS scores related to lifestyle factors. **Conclusions:** Lifestyle factors such as smoking, alcohol use, and poor hygiene do not significantly affect the time to symptom onset in osteodiscitis, but they are associated with a higher risk of complications. The management of postoperative osteodiscitis remains predominantly conservative with antibiotics, although surgical intervention may be necessary in cases of resistance or neurological complications. Proper follow-up is crucial for ensuring complete eradication of infections. **Keywords**: SPONDYLODISCITIS, SPINAL INFECTION, OSTEOMYELITIS, ANTIBIOTIC THERAPY, PAIN MANAGEMENT, SURGICAL INTERVENTION, CHRONIC INFLAMMATION.

INTRODUCTION

Infections of the lumbar spine may occur following surgical intervention on a degenerative spinal disc and can be either septic or aseptic in nature. Lumbar disc surgery, particularly discectomy proce-

dures, may lead to postoperative infections involving the intervertebral disc (discitis), the vertebral bodies (osteomyelitis), or both, referred to as osteodiscitis. These spinal pathologies seldom present in isolation and are typically encompassed under the term spondylodiscitis. Postoperative lumbar infections may further extend into the epidural space, facet joints, or paravertebral tissues.

Postoperative lumbar osteodiscitis is an uncommon yet serious complication, accounting for approximately 3-5% of cases. It must be carefully differentiated from primary vertebral endplate infections with secondary disc involvement. Therefore, the term spondylodiscitis or vertebral osteomyelitis is often more appropriate to describe this condition (1). The risk of postoperative spinal infection increases due to various preoperative, intraoperative, and postoperative factors, with incidence rates ranging from 0.7% to as high as 20% in some reports (2). Diagnosis of postoperative osteodiscitis relies on a multidisciplinary approach, integrating clinical symptoms, laboratory investigations, bacteriological cultures obtained via disc aspiration, and radiological findings (3-6). This condition represents a serious complication that can severely impair quality of life, resulting in neurological deficits, spinal deformities, or segmental instability (4-6).

A recent study in Denmark reported an increase in spondylodiscitis incidence from 2.2 to 5.8 per 100,000 individuals per year between 1995 and 2008, while in Germany, the estimated incidence ranged from 30 to 250,000 cases annually, based on data from the Federal Statistical Office in 2015 (7). In Western countries, the incidence remains under 1%, whereas in India, it ranges from 4% to 10% (8).

Postoperative osteodiscitis is a rare but severe complication following intervertebral disc surgery. This clinical entity was first described by Frank Turnbull in 1953 (9-11). It predominantly affects the lumbar spine, with single-level involvement observed in approximately 65% of cases, contiguous multilevel disease in 20%, and noncontiguous multilevel involvement in 10%. The condition typically manifests around 6 to 7 weeks post-discectomy and is often associated with incomplete surgical procedures or recurrent disc herniations (2-9). The infection may be septic-commonly due to contamination by skin flora such as Staphylococcus aureus—or aseptic, resulting from intraoperative trauma and vascular compromise of the disc. The latter may be associated with spinal tuberculosis, which spreads along the spinal ligaments and involves the anterior aspects of adjacent vertebral bodies, potentially leading to vertebral angulation and progressive kyphosis (12).

MATERIALS AND METHODS

This study is a descriptive cross-sectional analysis based on secondary data extracted from general clinical observation charts, collected between 2018 and 2024, at the Bucharest University Emergency Hospital and the Dr. Victor Babeș Clinical Hospital for Infectious and Tropical Diseases, Bucharest. A range of variables were recorded from these observation charts and compiled into a structured database for analysis.

The working hypothesis of this research is that specific patient-associated factors may influence the clinical course of osteodiscitis and contribute to the occurrence of its complications. Postoperative osteodiscitis often presents with nonspecific

clinical symptoms, and the majority of patients tend to receive a delayed diagnosis. The cornerstone of effective treatment for this infection lies in an accurate and timely diagnosis, which should always be based on a comprehensive correlation between the patient's clinical presentation, laboratory test results, and imaging findings.

The primary objective of this study is to evaluate the association between various factors and the development of osteodiscitis-related complications, based on a sample of 85 patients identified across two medical institutions in Bucharest during the specified period.

To ensure ethical compliance, informed consent for data protection and study inclusion was obtained and signed by each patient or, where applicable, their legal guardians. The study also involved cooperation with infectious disease departments outside the University Hospital, enabling follow-up of operated patients, and ensured access to preoperative and postoperative neuroimaging investigations.

The target population consisted of patients diagnosed with osteodiscitis and hospitalized after varying intervals from surgical intervention for disc herniation located at different levels within the thoracic, lumbar, and/or sacral spinal segments.

Statistical evaluation was performed based on patient subgrouping by age, sex, residence, education level, behavioral risk factors, and presence of comorbidities. Data were analyzed using the independent samples t-test to compare VAS scores and symptom onset timing between subgroups, and Welch's t-test was applied for comparing mean ages in groups with unequal variances. The Chi-square (X^2) test was used to assess the association between education level and area of residence. Normality was tested using the Shapiro-Wilk test, and variance equality with Levene's test. Statistical significance was considered at $p < 0.05$. Results were presented in structured tables and graphs to illustrate subgroup distributions and comparative outcomes.

The final study population comprised 85 consecutively hospitalized patients, with 64 cases recorded at the Bucharest University Emergency Hospital and 21 cases at the Dr. Victor Babeș Clinical Hospital**.**

RESULTS

The study included a total of 85 hospitalized patients diagnosed with postoperative osteodiscitis. Of these, 64 patients were admitted to the University Emergency Hospital Bucharest, while 21 patients were treated at the Dr. Victor Babeș Clinical Hospital for Infectious Diseases and Tropical Medicine.

With respect to sex distribution, among the 64 patients from the University Emergency Hospital Bucharest, 30 were female and 34 were male. At the Dr. Victor Babeș Clinical Hospital, 13 were female and 8 were male (fig. 1).

This distribution reflects a predominance of male patients in both medical institutions, with the overall male-to-female ratio slightly favoring men (42 males *vs*. 43 females).

The age distribution of the 85 patients included in this study was stratified into standard 5-year age intervals, highlighting the demographic structure of the cohort. As shown in the figure, the largest concentration of cases was observed in the 60-64, 65-69, and 70-74 age groups, with a predominance of female patients in these intervals.

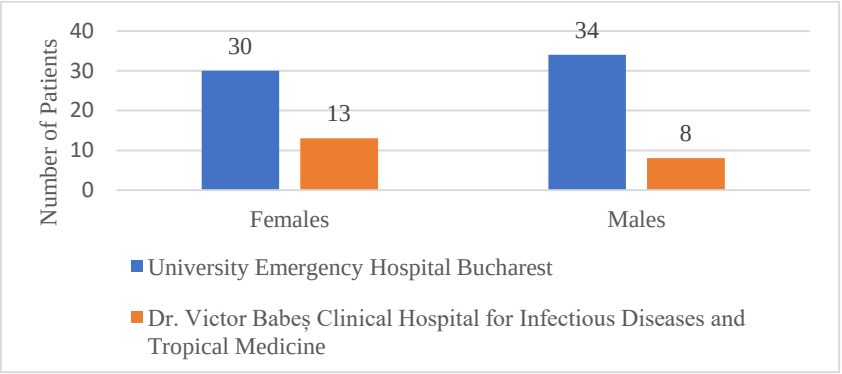

Fig. 1. Distribution of patients with postoperative osteodiscitis by sex and hospital of admission.

In contrast, male patients were more frequently represented in the older age groups (75-79 and 65-69), with a notable presence also in the 55-64 range. Fewer cases were recorded in the younger age brackets, with only isolated instances of patients under 40 years of age, indicating that postoperative osteodiscitis predominantly affects an older adult population, particularly those aged 55 and above (fig. 2).

This pattern supports the hypothesis that age-related comorbidities, immune senescence, and degenerative spinal pathology may contribute to increased vulnerability to postoperative infectious complications.

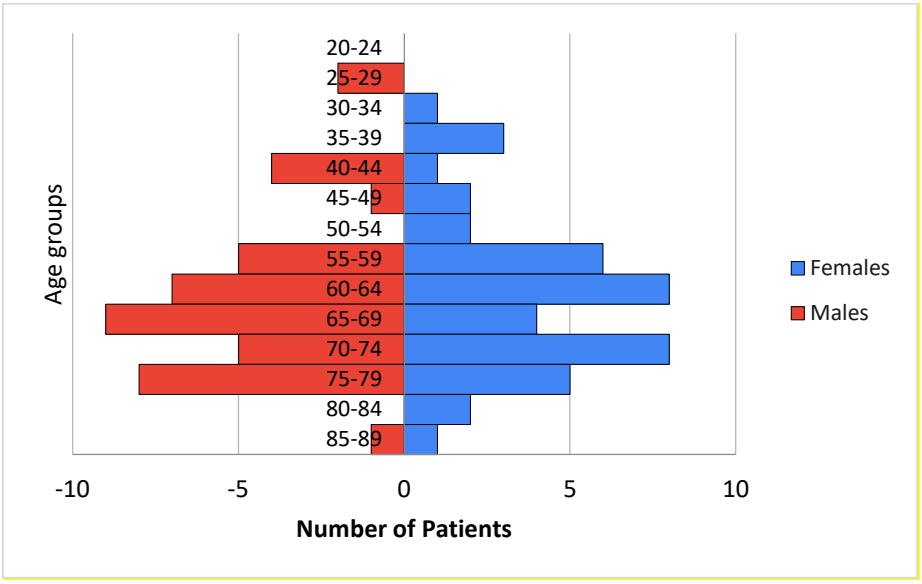

Fig. 2. Distribution of postoperative osteodiscitis patients by age group and sex. (Female patients represented in blue; male patients in red. Age groups are shown in 5-year intervals.)

The population analyzed in this study was also categorized based on their residential environment-rural or urban-and sex. Out of the total 85 patients (fig. 3):

- Among female patients, 24 resided in rural areas, while 19 were from urban areas.
- Among male patients, 23 had a rural residence, and 19 lived in urban areas.

This data indicates a slightly higher prevalence of osteodiscitis among patients from rural settings in both sexes. The marginal difference between rural and urban populations may reflect unequal access to timely surgical interventions, postoperative monitoring, or early diagnostic imaging in rural regions.

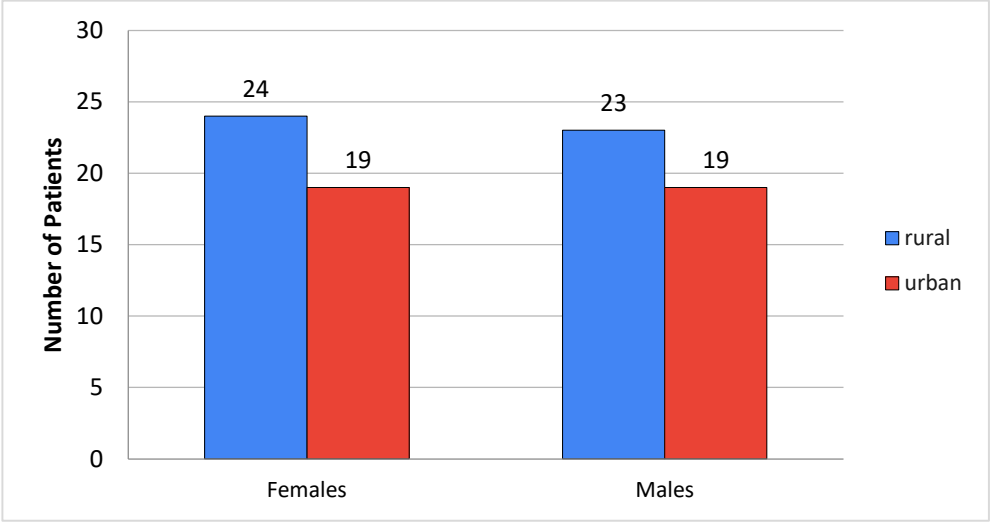

Fig. 3. Distribution of patients diagnosed with postoperative osteodiscitis by sex and area of residence. (Rural patients represented in blue; urban patients in red.)

In the assessment of predisposing conditions, several behavioral risk factors were identified among the patient cohort, with smoking, alcohol consumption, and poor hygiene emerging as the most frequently reported. A total of 13 patients were active smokers, making this the most prevalent behavioral factor in the study. Additionally, 7 patients reported chronic alcohol use, while another 7 exhibited poor personal hygiene, which may have contributed to increased microbial colonization or delayed postoperative healing (fig. 4)

These findings emphasize the importance of comprehensive preoperative screening that includes modifiable behavioral risk factors. Patient education and counseling prior to surgery could play a key role in lowering the incidence of postoperative complications such as osteodiscitis.

Average time until the onset of osteodiscitis symptoms varied depending on lifestyle-related factors. Symptoms appeared latest in smokers, at around 15.7 weeks, while non-smokers experienced symptoms earlier, at approximately 9.5 weeks. Similar trends were observed for patients with poor hygiene and those consuming alcohol, who developed symptoms slightly later compared to those without

these factors.

These differences were not statistically significant, indicating that lifestyle-related factors did not have a clear impact on the timing of symptom onset. No significant differences were observed between male and female patients either ($p \geq 0.05$) (Table 1).

Older patients were more likely to present with comorbidities (tab. II and fig. 5).

The number of patients with comorbid conditions was notably higher in the older age groups compared to those without comorbidities.

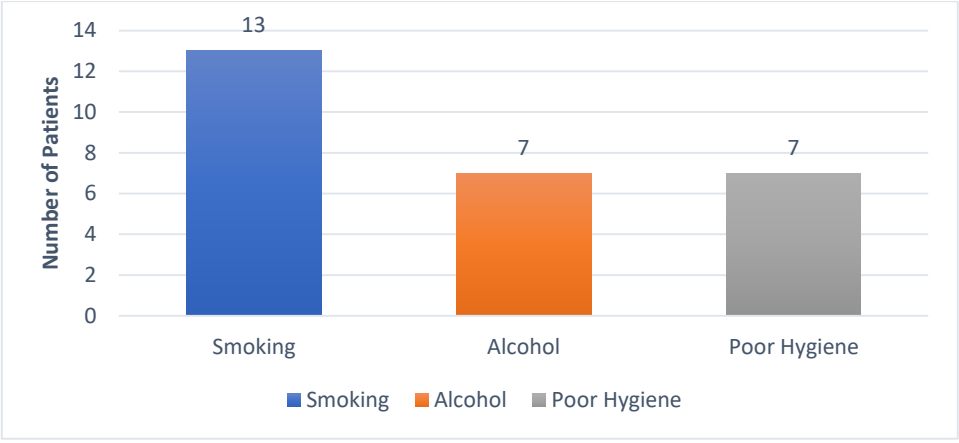

Fig. 4. Distribution of behavioral risk factors (smoking, alcohol consumption, and poor hygiene) among patients diagnosed with postoperative osteodiscitis.

TABLE I.

Average time (weeks) to symptom onset according to lifestyle-related factors in patients with postoperative osteodiscitis.

Lifestyle-related factor	The presence or absence of lifestyle- related factors	Mean duration (weeks) until symptom onset	Number of patients
Smoking	Smoking	15.69 (SD±12.399)	13
	Non-Smoking	9.53 (SD±7.083)	72
Alcohol	Alcohol Consumption	14.57 (SD±8.829)	7
	No Alcohol	10.10 (SD±8.241)	78
Poor Hygiene	Poor Hygiene	16.14 (SD±15.742)	7
	Normal Hygiene	9.96 (SD±7.291)	78
Total		**10.47 (SD±8.328)**	**85**

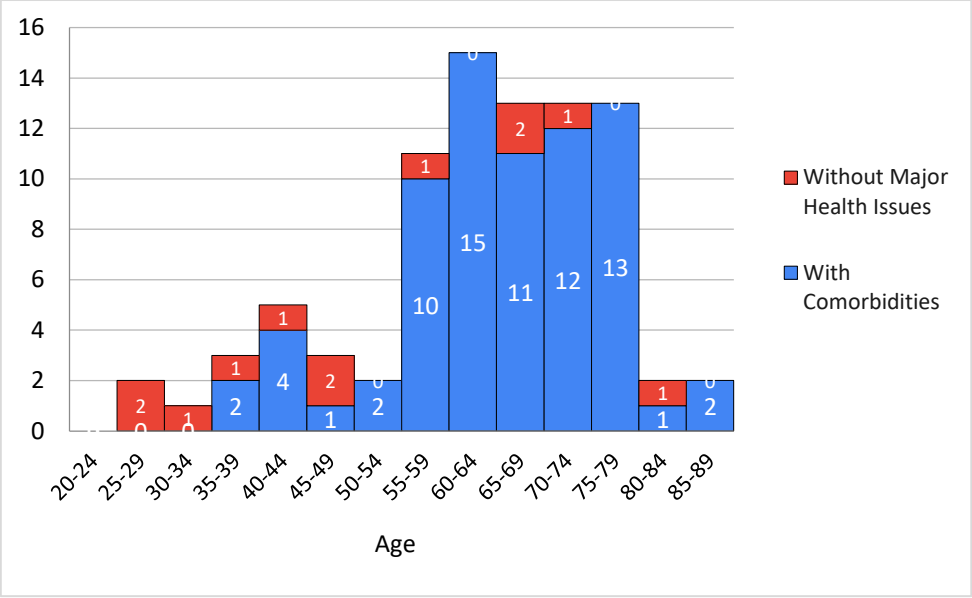

Fig. 5. Distribution of patients with and without comorbidities across age groups. (Blue bars indicate patients with comorbidities; red bars indicate those without major health issues.)

Patients with comorbidities had a higher mean age (65.15 years), compared to those without comorbidities (54.19 years), suggesting a possible age-related vulnerability to multiple health conditions in the postoperative context (tab. II).

TABLE II.

Presence of comorbidities and mean age of patients with postoperative osteodiscitis

Comorbidities	Number of Patients	Median Age
Yes	69	65.15 (SD±10.403)
No	16	54.19 (SD±18.985)
Total	**85**	**62.64 (SD±13.548)**

Patients from urban areas were more likely to have higher education, with a greater frequency of individuals holding university degrees compared to those with only secondary education. In contrast, patients from rural areas predominantly had medium-level education, with significantly fewer reporting higher education qualifications.

The association between education level and area of residence was found to be statistically significant (Chi-square test, $p < 0.05$) (fig. 6).

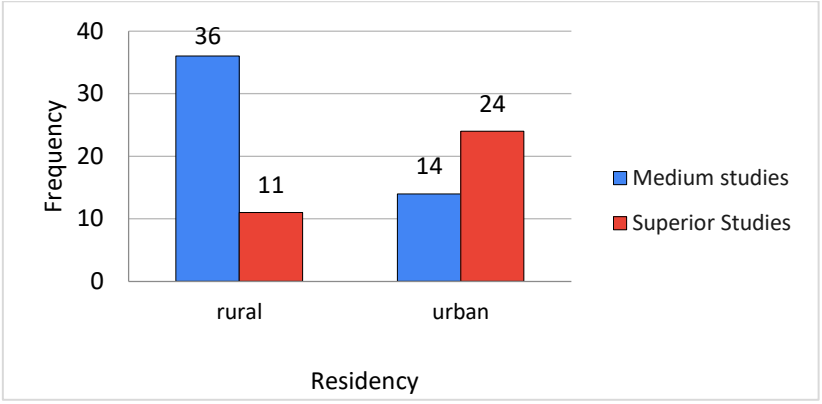

Fig. 6. Distribution of education level by area of residence among patients with postoperative osteodiscitis.

Pre-treatment VAS scores tended to be higher among patients who reported alcohol consumption, while lower average scores were observed in non-smokers and those without alcohol use. Despite these numerical differences, the variations in both pre-treatment and post-treatment VAS scores across all risk factor categories-including smoking, alcohol use, and poor hygiene-were not statistically significant (independent samples t-test, $p \geq 0.05$).

This suggests that the presence of these lifestyle-related risk factors did not significantly influence pain intensity as measured by the VAS scale, either before or after treatment in the studied population (tab. III).

TABLE III.

Distribution of patients according to risk factors and their pre-treatment and post-treatment VAS scores.

Gender	Risk Factors	Presence of Risk Factors	Number of Patients	Pre-treatment VAS score	Vas Score Post-Treatment
Females	Smoking	Yes	7	7.43 (SD±1.512)	3.43 (SD±2.370)
		No	36	7.69 (SD±1.327)	4.50 (SD±2.063)

		No	78	7.76 (SD±1.261)	4.44 (SD±1.931)
Total			**85**	**7.76 (SD±1250)**	**4.40 (SD±1.904)**

Postoperative VAS scores decreased in all subgroups, regardless of gender or the presence of lifestyle-related risk factors. On average, the mean VAS score dropped from 9.83 preoperatively to 7.71 postoperatively in patients without poor hygiene, and from 9.86 to 7.57 in smokers.

Although alcohol users had the highest preoperative and postoperative VAS scores (10.00 and 9.00, respectively), this group had a very small sample size (n=3), limiting the interpretability. Patients without alcohol consumption had a more notable pain reduction, from 9.80 to 7.60. Across all groups, the pain reduction averaged around 2 points on the VAS scale (tab. IV).

DISCUSSION

In current spine surgery literature, the sudden onset of severe pain following a pain-free interval after lumbar discectomy often raises suspicion for recurrent disc herniation. However, this distinction is typically made through MRI evaluation only after a 6-month postoperative period. In the present study, all patients showed clinical improvement within the first eight weeks, regardless of treatment strategy. Follow-up was conducted systematically using blood tests or plain radiographs at 1, 3, 6, and 12 months post-discharge, and then annually. Fusion status was assessed between 6 and 12 months via radiography and computed tomography. Importantly, no neurological deficits were observed during either conservative or surgical treatment phases.

Patients who underwent surgical intervention reported a higher rate of satisfaction at the 12-month follow-up compared to those managed conservatively. This group also benefited from significantly shorter hospital stays, reduced periods of bed rest, a quicker tapering of antibiotic regimens, and earlier relief of clinical symptoms. However, surgery was associated with higher overall costs-including the need for blood transfusions-and a higher complication rate, as supported by existing studies (3, 7).

The treatment of postoperative osteodiscitis relies primarily on targeted antibiotic therapy initiated after biopsy and guided by pathogen identification, cultures, and sensitivity profiles. Strict bed rest, nutritional support, analgesics, orthotic bracing, and physical therapy are also essential components of the conservative management strategy. Immobilization of the affected spinal segment, commonly using a rigid brace, is typically recommended for approximately two weeks or until acute pain subsides. Numerous studies have demonstrated that long-term conservative treatment can achieve success rates ranging between 70% and 83% (3, 4, 9, 13-17).

Some authors advocate for early surgical intervention, particularly via debridement followed by antibiotics, arguing it may yield better outcomes than antibiotics alone. In cases where treatment is initiated within two weeks of symptom onset, six weeks of antibiotic therapy is often considered sufficient for resolution (3, 4, 5, 7, 18).

These findings collectively underscore the importance of early diagnosis, individualized therapeutic decision-making, and multidisciplinary management to optimize outcomes in patients with postoperative osteodiscitis.

CONCLUSIONS

Lifestyle-related factors such as alcohol consumption, smoking, and poor hygiene were identified in 27 out of the 85 patients included in the study, with smoking being the most frequently observed. No statistically significant differences were found in the time to symptom onset between subgroups based on the presence or absence of these risk factors. Although higher pre-treatment VAS scores were noted among alcohol users and lower scores among non-users and non-smokers, these differences were not statistically significant either. However, the presence of at least one lifestyle-related risk factor (smoking, alcohol use, and/or poor hygiene) was significantly associated with

the development of complications.

The diagnosis of postoperative lumbar osteodiscitis should rely on a combination of clinical history, physical examination, biochemical markers, and appropriate neuro-radiological imaging, particularly MRI. Most cases can be successfully managed with conservative antibiotic therapy, guided by the identification and sensitivity profile of the responsible pathogen. Surgical intervention is reserved for patients who fail to respond to conservative treatment, those with antibiotic-resistant infections, and those presenting with neurological complications such as acute paraplegia, intractable lumbar pain, sepsis, abscess formation, spinal instability, or severe kyphosis.

Long-term follow-up extending up to one year postoperatively is essential to ensure complete eradication of the infection and to monitor for potential late-onset complications (2, 19-23).

THE IMPORTANCE OF CONTINUOUS GLUCOSE MONITORING (CGM) AND DIETARY DECISIONS IN GESTATIONAL DIABETES MELLITUS (Abstract): Gestational diabetes mellitus (GDM) poses significant risks to both the mother and fetus if not managed appropriately. Continuous glucose monitoring (CGM) provides comprehensive glycemic profiles that support individualized dietary interventions. **Materials and methods:** We discuss here about 44 pregnant women diagnosed with GDM, illustrating how CGM data can be used to optimize glycemic control through specific nutritional strategies. Continuous interstitial glucose measurements were obtained using the Dexcom ONE+ CGM sensor, with monitoring initiated at 27-28 weeks and continued through 39 weeks of gestation. **Results:** Fasting blood glucose averaged 112 mg/dL. One-hour postprandial glucose differed by meal type (ANOVA, $p<0.001$), with high-carbohydrate meals producing the highest values, followed by fruits, protein/low-carb meals and snacks (Tukey *post-hoc*). Two-hour postprandial glucose showed a similar pattern (ANOVA, $p<.001$). Differences between CGM readings and true glucose levels were larger in participants who experienced false low-glucose alarms, and this difference was statistically significant (t-test, $p<0.001$). **Conclusions:** Our data highlights the value of integrating CGM technology with personalized nutritional plans in the effective management of GDM. **Keywords:** GESTATIONAL DIABETES MELLITUS, CONTINUOUS GLUCOSE MONITORING, DIET.

INTRODUCTION

Gestational diabetes mellitus (GDM) is a type of hyperglycemia diagnosed or developed during pregnancy, often divided into classes of diet-controlled and pharmacological treatment. Identification of GDM is crucial because it increases the risk of developing type 2 diabetes in the long term and reduces adverse pregnancy outcomes. However, there is no consensus on the diagnostic criteria for GDM or the optimal timing of pregnancy screening. Approaches to the management of GDM have evolved over several decades because of the high rates of perinatal mortality among women with diabetes during pregnancy (1, 2).

According to a recent assessment by the International Diabetes Federation, GDM has been diagnosed in 1 in 6 live births worldwide. Approximately 7% of pregnancies in the United States are complicated by some type of diabetes, with GDM accounting for 86% of these cases. In Europe, the estimated prevalence of GDM is 10.9% (3). The evolution of diagnostic criteria has reflected ongoing scientific research and changing standards in maternal-fetal medicine. The release of placental hormones causes marked insulin resistance, with human placental lactogen being the main hormone associated with increased insulin resistance. In patients with GDM, conditions or factors cause maternal pancreatic β-cell dysfunction or delayed β-cell response, leading to decreased insulin secretion and maternal hyperglycemia. Maternal obesity in early pregnancy, due to higher levels of free fatty acids, also promotes abnormally increased insulin resistance. Genetic etiology has also been discovered in some studies on DGM, with several studies discovering genetic polymorphisms involved in functions such as insulin secretion, glucose metabolism, and insulin resistance in patients with type 2 diabetes (1, 3, 4, 5).

Frequent glucose monitoring is crucial for achieving optimal glycemic control, especially during pregnancy. The American Diabetes Association recommends at least daily fasting and postprandial testing, with a minimum of four tests per day (6). However, adherence to traditional self-monitoring of blood glucose (SMBG) is often suboptimal due to barriers such as pain, inconvenience, disruption of daily activities, and social stigma. Pregnant women with gestational diabetes (GDM) also face difficulties completing the prescribed testing regimen, leading to increased preeclampsia and higher HbA1c levels at delivery (7, 8, 9, 10).

CGM, or continuous glucose monitoring, is now considered ideal for managing blood glucose levels in people with type 1 diabetes (T1D) and T2D treated with intensive insulin therapy, basal insulin therapy, and patients with a history of severe hypoglycemia. CGM measures interstitial glucose levels and transmits readings to the user's smartphone app or wearable receiver every 1 to 5 minutes. It displays trend arrows that indicate the direction and rate of change in glucose levels and can predict glucose changes over the next 20 to 60 minutes. It has been shown to lower HbA1c, reduce severe hypoglycemic events, increase time in target glucose range, and reduce time in hypoglycemic ranges (6, 11).

This study aims to investigate the management of gestational diabetes mellitus (GDM) in by utilizing continuous glucose monitoring (CGM) technology, specifically the Dexcom system, with nutritional surveillance.

MATERIALS AND METHODS

This study focused on the evaluation of glucose variability and the influence of diet in 44 pregnant women with gestational diabetes mellitus (GDM). By analyzing their glucose trends along with food intake, this study aimed to understand how real-time glucose data can guide dietary choices, improve glycemic control, and support the overall management of GDM during pregnancy.

The participants used a Dexcom ONE+ CGM sensor (Dexcom, Inc., San Diego, CA) to continuously record interstitial glucose values from March 23rd to June

10th, 2025. The Dexcom ONE+ is a compact, discreet, and reliable continuous glucose monitoring system for type 1, type 2, and gestational diabetes (12). The sensor, worn on the back of the upper arm, continuously measured interstitial glucose levels every five minutes for up to 10 days. The data were transmitted in real time to the Dexcom ONE mobile application, allowing participants to view glucose trends, set personalized alerts, and record daily events such as meals, snacks, and exercise.

During the follow-up period, data on blood glucose levels and food intake were collected and subsequently analyzed to assess glucose response to specific meals, time in range (defined as 70-140 mg/dL, according to recommended targets for gestational diabetes), glycemic variability, and patterns of hyperglycemia or hypoglycemia.

All participants were diagnosed with GDM and were monitored from 27-28 weeks of gestation until 39 weeks. The mean body mass index (BMI) of the cohort was 29.5, classifying them on average as overweight according to World Health Organization (WHO) criteria (13). The diagnosis was established based on standard oral glucose tolerance test (OGTT) criteria. OGTT results demonstrated elevated fasting plasma glucose (mean = 116 mg/dL, reference target <95 mg/dL) and 1-hour post-load glucose (mean = 165 mg/dL, reference target <140 mg/ dL), while 2-hour post-load glucose remained within normal limits (mean = 99 mg/dL, reference target <115 mg/dL). These findings met the diagnostic threshold for GDM.

RESULTS

Fasting blood glucose (FBG) values ranged from 83 to 97 mg/dL, with a mean of 112 mg/dL(SD=5), reflecting generally well controlled basal glycemia prior to meals.

A One-way ANOVA analysis was conducted, and it revealed a significant effect of meal type on 1-hour postprandial glucose (PPG_1h), $F(3, 40) = 488.231$, $p<0.001$. Post-hoc comparisons using the Tukey HSD test indicated that high-carbohydrate meals resulted in significantly higher glucose levels (M = 150.92 mg/dL, SD = 2.42) than protein/low-carb meals (M = 115.25 mg/dL, SD = 3.79), snacks (M = 110.5 mg/dL, SD = 2.17), and fruits (M = 130.4 mg/dL, SD = 2.22) (fig. 1).

In addition, a similar pattern was observed for 2-hour postprandial glucose (PPG_2h). One-way ANOVA showed a significant effect of meal type, $F(3, 40) = 223.764$, $p<0.001$, with Tukey post-hoc comparisons revealing that high-carbohydrate meals (M = 111.92 mg/dL, SD = 1.85) produced higher glucose levels than fruits (M = 103.6 mg/dL, SD = 2.22), protein/low-carb meals (M = 95.33 mg/dL, SD = 2.57), and snacks (M = 89.90 mg/dL, SD = 1.82) (fig. 2).

CGM measurements revealed discrepancies compared to glucometer readings. Participants without false hypoglycemic alarms had a mean CGM difference of 23.19 mg/dL (SD = 0.89), whereas participants experiencing false alarms had a mean difference of 28.71 mg/dL (SD = 0.72). An independent-samples t-test was conducted to compare the difference between CGM and glucometer readings in participants. Levene's test indicated that the assumption of equal variances was met, $F = 0.693$, $p = 0.410$. The t-test revealed a significant difference between the groups, $t(44) = -20.31$, $p<0.001$, with a mean difference of -5.53 mg/dL (95% CI [-6.08, -4.98]) (fig. 3).

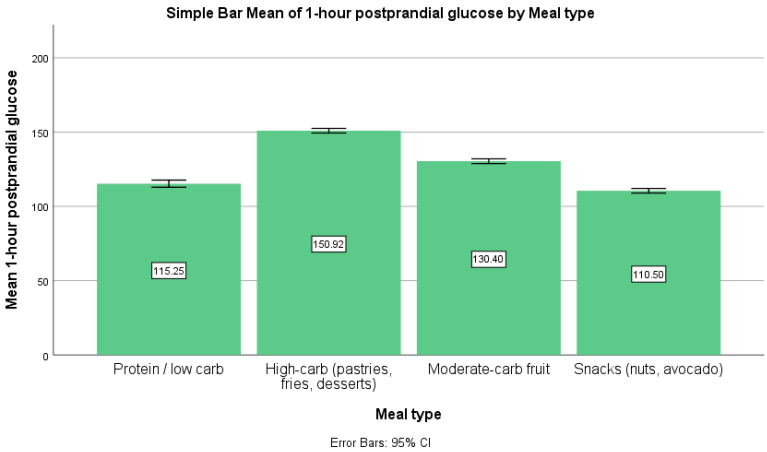

Fig. 1. Mean 1-hour postprandial glucose levels (mg/dL) by meal type in 44 pregnant women with gestational diabetes mellitus. Error bars represent ± standard deviation. One-way ANOVA revealed a significant effect of meal type on 1-hour glucose, $F(3, 40) = 488.231$, $p<0.001$. Tukey HSD post-hoc tests showed that high-carbohydrate meals had higher glucose than protein/low-carb meals (-35.67 mg/dL, $p<0.001$), fruits (-20.52 mg/dL, $p<0.001$), and snacks (-40.42 mg/dL, $p<0.001$). Fruits were higher than protein/low-carb meals (15.15 mg/dL, $p<0.001$) and snacks (19.90 mg/dL, $p<0.001$). Snacks were higher than protein/low-carb meals (4.75 mg/dL, $p = 0.002$).

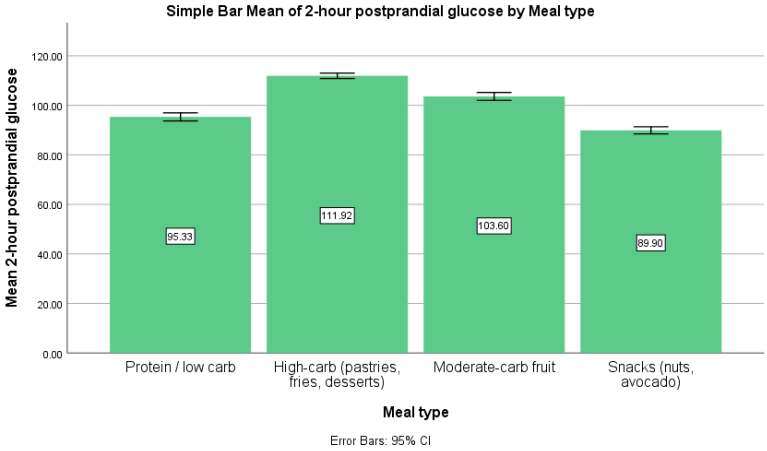

Fig. 2. Mean 2-hour postprandial glucose levels (mg/dL) by meal type in 44 pregnant women with gestational diabetes mellitus. Error bars represent ± standard deviation. One-way ANOVA showed a significant effect of meal type on 2-hour glucose, $F(3, 40) = 223.764$, $p<0.001$. Tukey HSD post-hoc tests indicated that high-carbohydrate meals resulted in higher glucose than protein/low-carb meals (16.67 mg/dL, $p<0.001$), fruits (8.40 mg/dL, $p<0.001$), and snacks (22.00 mg/dL, $p<0.001$). Fruits resulted in higher glucose compared to protein/low-carb meals (8.27 mg/dL, $p<0.001$) and snacks (13.60 mg/dL, $p<0.001$). Snacks were higher than protein/low-carb meals (5.33 mg/dL, $p<0.001$).

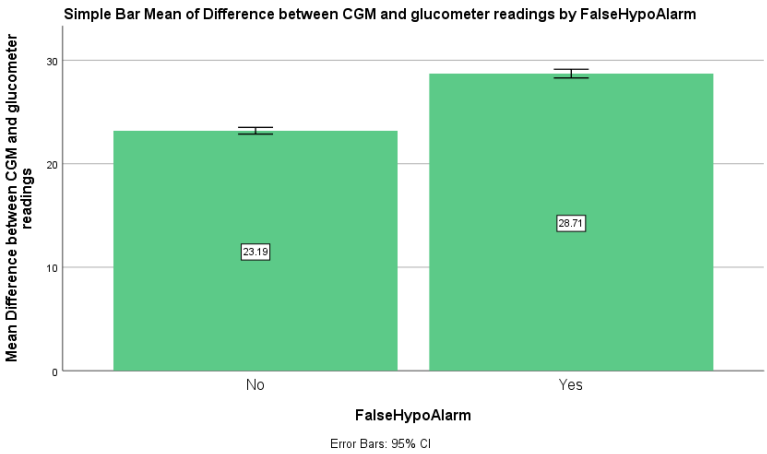

Fig. 3. Mean difference between CGM readings and glucometer measurements (mg/dL) in participants with and without false hypoglycemic alarms. Error bars represent ± standard deviation. Independent-samples t-test showed a significant difference, t (44) = -20.31, p<0.001, with participants experiencing false alarms having higher CGM discrepancies (28.71 ± 0.72 mg/dL) than those without false alarms (23.19 ± 0.89 mg/dL).

DISCUSSION

Our data illustrates how continuous glucose monitoring (CGM), combined with personalized dietary interventions, can effectively guide clinical decisions to improve glycemic control in GDM. Participants' glycemic profiles revealed significant differences in postprandial glucose depending on meal type, with high-carbohydrate meals produced significantly higher 1-hour and 2-hour postprandial glucose levels compared with protein / low-carbohydrate meals, snacks, and fruits, which showed lower postprandial values (ANOVA and Tukey *post-hoc*, p<0.001).

Postprandial hyperglycemia after ingestion of refined carbohydrates and high-fat meals reflects previous research findings emphasizing the impact of meal composition on glucose fluctuations in GDM (14, 15). Similarly, CGM measurements showed slightly larger discrepancies in participants experiencing false low-glucose alarms, confirming the t-test result (p<0.001).

In contrast, meals rich in fiber, protein, and unsaturated fat - such as vegetables, nuts, avocados, and dairy - were associated with improved glycemic control, consistent with randomized controlled trials demonstrating the benefits of low-GI, high-fiber diets in the management of GDM (16).

Body weight remained relatively stable across participants, consistent with dietary and activity patterns. These dietary patterns not only attenuate postprandial glucose peaks but also contribute to satiety and improved insulin sensitivity (17). This data supports the clinical focus on dietary counseling tailored to individual glycemic responses, made more feasible by CGM technology.

Challenges associated with CGM accuracy, particularly false hypoglycemia alarms and calibration issues, have been documented in other studies (9, 18). These findings emphasize the need for healthcare providers to integrate CGM data with capillary glucose measurements and clinical judgment.

Despite these limitations, CGM offers unparalleled granularity in glucose monitoring, allowing for real-time feedback and more precise dietary adjustments (19, 20).

Taken together, these aspects reinforce current guidelines that advocate for personalized strategies for managing GDM, combining technology (CGM) and diet optimization (6). This also opens new discussions about the use of AI in nutritional epidemiology (21, 22). Future research should focus on larger cohorts to validate the utility of CGM in predicting adverse outcomes and refining dietary recommendations based on individual glycemic responses.

CONCLUSIONS

Our data highlights the critical role of continuous glucose monitoring (CGM) combined with personalized dietary management in optimizing glycemic control in gestational diabetes mellitus (GDM). CGM use allowed identification of meal types that produced higher postprandial glucose levels, while protein/low-carbohydrate meals and snacks were associated with more stable glycemia. CGM provided more detailed glucose monitoring than standard glucometer readings, highlighting its value for guiding real-time clinical decisions. Future studies should investigate CGM-guided dietary strategies in larger cohorts to validate these findings and refine recommendations for GDM management.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

PATIENT CONSENT STATEMENT

The participants provided informed consent for the use of their anonymized medical data for educational and research purposes. No medical actions were implemented based on the data obtained, and all care decisions were made by her obstetric care team.

THE CITY EFFECT: HOW URBAN LIVING SHAPES PSYCHOTIC RELAPSE RISK (Abstract): Urbanization is a rapidly intensifying global trend and a significant determinant of population mental health. Growing evidence demonstrates that individuals exposed to urban environments experience a markedly higher risk of developing psychotic disorders, particularly schizophrenia, with effects that show clear dose-response patterns based on timing and duration of exposure. This study **aimed** to examine relapse burden in a hospital-based cohort of patients with psychotic disorders, with particular focus on urban residence and environmental correlates. **Materials and methods:** We conducted a six-month observational cross-sectional study including 60 hospitalized patients with schizophrenia-spectrum or acute psychotic disorders. Relapse vulnerability was operationalized using prior psychiatric hospitalizations. A subgroup of 31 patients underwent depressive symptom assessment and biomarker analysis, alongside 19 healthy controls. Sociodemographic, lifestyle, and environmental exposures were recorded. Descriptive statistics and correlation analyses were performed. We complemented the observational findings by a targeted literature synthesis. **Results:** Half of our cohort had 3 or more hospitalizations, indicating substantial relapse burden. Within the acute psychotic subgroup, 65% were of urban origin. Smoking (41.7%) and occupational chemical exposure (16.7%) were notable environmental factors. The predominance of urban residence among relapse-prone patients aligns with epidemiological evidence supporting an exposure-gradient relationship between urbanicity and psychosis. **Conclusions:** Urbanicity appears to function as a cumulative environmental correlate of psychotic relapse. Integrating epidemiological, psychosocial, and neurobiological perspectives may inform targeted prevention strategies and urban mental health policies aimed at reducing relapse risk. **Keywords**: URBANICITY, PSYCHOSIS, SCHIZOPHRENIA, STRESS.

INTRODUCTION

Urbanization represents a major demographic shift of the century with projections estimating that two-thirds of the population will be urban by 2050 (1). This change has paramount implications for public mental health (2, 3). Emerging evidence demonstrates a consistent link between urbanicity and increased risk of psychotic disorders, particularly schizophrenia (2-4).

Studies dating back to 1939 have con-

sistently reported an increased prevalence of psychosis in densely populated socially disorganized urban areas (4). These findings have been replicated by modern large-scale cohort studies across Europe and North America (5). Additionally, a dose-response association between urban living and psychosis has been established, since prolonged urban exposure in early life leads to higher psychosis likelihood later in life (6).

This association is multifactorial, involving interactions between social, environmental, and biological processes (7). Numerous psychosocial adversities are concentrated within urban areas (i.e. social fragmentation, deprivation, minority stress, and exposure to violence) (7).

Important neurobiological changes occur in the context of urbanicity (8). A central hypothesis is that chronic exposure to urban stressors potentiates sensitization of stress-response circuits, particularly HPA axis and mesostriatal dopaminergic pathways (3, 9). Urban upbringing has been associated with hypercortisolemia and heightened HPA axis reactivity in both healthy individuals and those at high risk for psychosis (4). Chronic activation of the HPA axis may lead to glucocorticoid dysregulation, hippocampal vulnerability, and exaggerated responses to daily stressors (1, 10). Individuals raised in urban areas show stronger amygdala and perigenual anterior cingulate cortex activation during social stress tasks, suggesting heightened threat sensitivity (8). These stress-induced neural alterations mirror patterns seen in individuals with prodromal or established psychosis (6). Furthermore, urbanicity is strongly associated with increased striatal dopamine synthesis capacity, a core biological abnormality in schizophrenia (4, 8, 9). Positron-emission tomography (PET) imaging studies show that individuals exposed to urban environments demonstrate greater mesostriatal dopaminergic responsivity to stress (8, 9). This dopaminergic sensitization appears to mediate the link between social defeat and psychosis (3, 8, 9). Migrant status, minority stress, and chronic social exclusion also correlate with increased dopaminergic firing (4).

Despite decades of research, the mechanisms that connect urbanicity to psychotic outcomes remain only partially elucidated, while the burden of psychosis in cities continues to grow (1). A better understanding of these pathways is crucial for targeted public health interventions, reshaping urban environments, and improving outcomes for high-risk populations (4). Concurrently, we must acknowledge the role of mental health services in preventing psychotic decompensations (4). Counteracting the cumulative effects of urban stress requires accessible and culturally sensitive mental health services (4). Coordinated specialty care (e.g. assertive community treatment, family therapy, and integrated psychosocial support) reduces relapse and improves long-term functioning in psychotic disorders (1, 11). Early intervention services for individuals at high clinical risk can delay or prevent the evolution of prodromal symptoms to full psychosis, particularly in urban settings (6, 11). Mobile crisis teams and home-visiting programs are essential for patients who struggle with adherence or experience social isolation in dense city environments (12). Considering that every child is a developing adult, preventive strategies should target high-risk developmental periods, when urban stressors exert the strongest neurobiological effects (4,

13). In this regard, public health strategies should integrate mental health indicators into urban development frameworks to ensure that infrastructure decisions account for their psychological impact (7, 11). Consequently, these strategies may facilitate the improvement of patients' quality of life in the context of their own cultural and value systems (1, 14, 15).

The aim of our study was to characterize relapse vulnerability in a hospital-based cohort of patient with psychotic disorders by examining socio-demographic, lifestyle, and environmental factors, with a particular focus on urbanicity as a cumulative exposure correlate. We used prior psychiatric hospitalization history as a proxy for relapse burden, we described relapse-pattern distributions and evaluated candidate modifiers such as smoking and occupational chemical exposure. These observational findings were complemented by a targeted synthesis of current evidence on the mechanisms linking urban environments to psychosis onset and relapse, integrating epidemiological, psychosocial, neurobiological, and policy-level perspectives.

MATERIALS AND METHODS

We conducted a hospital-based observational cross-sectional study, complemented by a synthesis of current literature. Our study was performed at Socola Institute of Psychiatry over a recruitment period of approximately six months, allowing continuous monitoring of psychiatric admissions.

The primary observational cohort consisted of 60 hospitalized patients diagnosed with schizophrenia-spectrum disorders or acute psychotic disorder who fulfilled predefined inclusion and exclusion criteria. Within the larger cohort, a clinically characterized subgroup of 31 patients diagnosed with acute psychotic disorder was further analyzed for biological and symptom-related correlation. A control group of 19 individuals without psychiatric or inflammatory pathology was included for comparative purposes in the biomarker analyses.

Inclusion criteria consisted of: patients over the age of 18, diagnosis or acute psychotic disorder, voluntary hospitalization and written informed consent, Hamilton Depression Rating Scale (HAMD) score $\geq$ 26, absence of active inflammatory somatic disease, no recent surgery or vaccination in the previous three months, minimum basic education level ($\geq$ 8 completed classes). Exclusion criteria were represented by: major endocrine dysfunction, substance abuse capable of altering hormonal or inflammatory markers, severe chronic somatic illness, inability to provide informed consent.

All participants underwent structured clinical evaluation. Depressive symptom severity was measured using HAMD. In the acute psychotic subgroup, inflammatory and hormonal biomarkers were assessed using standardized laboratory methods, with blood sampling performed under controlled conditions.

Data were entered into a secured database and analyzed using SPSS software. Descriptive statistics were used to characterize socio-demographic and clinical variables. Categorical variable was expressed as absolute numbers and percentages. Correlation analysis (Pearson coefficient) was applied for continuous biological and clinical variables. Given the observational cross-sectional design, analyses were exploratory and descriptive in nature, without causal inference.

To complement the observational findings, a targeted narrative review was conducted using PubMed, Scopus, and Google Scholar. The search strategy included combinations of the following terms: urbanicity, urban environment, psychotic disorder, psychotic relapse, and psychotic decompensation. Only English-language, peer-reviewed publications were included. The aim of this addition was to integrate epidemiological, psychosocial, and neurobiological evidence regarding urban exposure and psychosis relapse into the interpretation framework of the observational findings.

RESULTS

The observational cohort comprised 60 hospitalized patients diagnosed with schizophrenia-spectrum disorders or acute psychotic disorder. Within this group, 31 patients with acute psychotic disorder underwent biomarker and depressive symptom assessment, alongside a control group of 19 individuals without psychiatric or inflammatory pathology.

Relapse vulnerability was operationalized using prior psychiatric hospitalization history. The distribution was as follows: 20 patients (33.3%) had 1-2 prior hospitalizations, 18 patients (30%) had 3-5 prior hospitalizations, and 12 patients (20%) experienced over 5 hospitalizations. Collectively, 50% of the cohort had at least 3 prior admissions, indicating a substantial subgroup with recurrent or chronic psychotic decompensation. This tendency toward higher admission frequency suggests a non-random concentration of relapse burden within the sample and supports the interpretation of the cohort as relapse-prone rather than first-episode predominant.

In the acute psychotic subgroup, Pearson correlation analysis between TNF-α and HAMD score revealed a negligible linear association ($r = 0.06310$) and a statistically non-significant result ($p > 0.005$). Therefore, at least in this subgroup, inflammatory burden, does not independently account for depressive symptom intensity in acute psychosis. This finding supports a multifactorial vulnerability model rather than a single biomarker-driven mechanism.

Within the acute psychotic subgroup (n=31), 65% (n=20) resided in urban areas, compared to 35% (n=11) from rural environments. Large-scale epidemiological studies have consistently showed that the incidence of psychosis is higher in densely populated cities compared to rural regions with effects sizes ranging from 1.5- to 3-fold according to the specific urban context (4, 6). This association is independent of socioeconomic factors, family psychiatric history, and substance use (1, 3). However, psychotic risk is dependent on the length of exposure, being minimal for individuals born and raised in rural areas, increasing for those from suburban zones, and maximal for patients living in inner cities (1, 4, 6). Moreover, early life can be highlighted as a critical period during which urban-related stressors may shape stress reactivity systems and neurodevelopment (1, 7). In this respect, longer exposure during childhood and early adolescence heightens psychotic vulnerability considerably (1, 3). Although inferential testing between urbanicity and hospitalization frequency was limited by available aggregated data, the predominance of urban origin within a clinically unstable subgroup is consistent with an exposure-gradient hypothesis. The descriptive over-representation of urban residents among relapse-prone patients aligns with the aforementioned epidemiological models.

Cross-cultural studies strengthen the association between urbanicity and psychosis with both Western European and North American cohorts reporting a higher incidence for schizophrenia and non-affective psychoses for residents of urban centers (1, 3, 4). Moreover, similar patterns have been observed in low- and middle-income countries, where urbanization is rapid and associated with social inequality, making it apparent that the link between psychotic disorders and urban living transcends economic, social, cultural, and healthcare contexts (7, 16). Additionally, migration leads to a two- to four-fold increase in psychosis rates in migrant residents, particularly of the second generation, of large cities compared to natives (1, 4). This is especially frequent when the migrants belong to socially marginalized ethnic or cultural groups (1, 4, 7).

Numerous social and environmental risk factors are concentrated within urban areas (3). However, they do not act independently, but rather cumulatively to increase psychotic risk (3, 7). One of the main factors we were able to identify is social fragmentation, characterized by high residential mobility, single-person households, and weak neighborhood cohesion (4, 17). This phenomenon is widely associated with higher admission rates for first-episode psychosis and psychotic relapses (4). In addition to social fragmentation, social isolation raises the risk of psychotic relapse through decreased social buffering, increased sensitivity to stressors, and increased loneliness (7, 18). At the same time, perceived social exclusion may intensify threat vigilance and internalized stigma, destabilizing individuals that are predisposed to psychotic relapse (19, 20). Along the same lines, social deprivation (i.e. unemployment, poor educational attainment, housing instability, and material poverty) amplifies psychosocial stress by increasing social comparison, reducing perceived control, and inducing chronic hypervigilance (1, 3). All of the latter are known factors that might destabilize vulnerable individuals and increase the risk of psychotic relapses (3). This vulnerability appears to be more important in young-to-middle adulthood. In the acute psychotic disorder subgroup 71% of the patients (n=22) were between 20-40 years, representing the peak psychosis relapse years. This result reduces confounding from geriatric comorbidity, since only one patient (3%) was over 61 years.

Deprivation may also influence psychical neighborhood quality, including chronic noise exposure, crowding, substandard housing, and lack of safe areas, which contribute to cumulative psychosocial stress (1, 21). Consequently, deprivation is a contributive factor to victimization and high crime rates (1, 3, 22). The former acts as an acute stressor that may precipitate relapse in individuals with pre-existing vulnerability (1, 22). In this regard, exposure to community violence has been shown to disrupt sleep, alter cortisol rhythms, and impair emotional regulation, all contributing to psychosis (22, 23). Not least, high urban density raises exposure to noise, crowding, and overstimulation, which dysregulate stress response and increase psychosis vulnerability (1, 6). Sensory overload, whether by constant auditory stimuli, frequent interpersonal proximity, or visual complexity, can contribute to cognitive fatigue and perceptual instability, particularly in high-risk individuals (3, 24, 25). Chronic noise exposure has been identified as not only a precipitant for psychotic

relapses, but also for triggering other known risk factors for psychosis such as sleep disturbance and circadian dysregulation (26, 27). Additionally, we identified occupational exposure to toxic chemical environments to be another risk factor that is more prevalent in urban areas. In our cohort, 16.7% (n=10) of patients reported occupational exposure to toxic chemical environments. While numerically smaller than the smoking subgroup, this exposure category represents a discrete environmental risk subset. Given its lower prevalence, statistical power for subgroup comparison is limited. However, the presence of nearly 1 in 6 patients underscores the role of environmental factors in relapse.

We also identified substance use and medication non-adherence as key precipitants of psychotic relapse. In our cohort, 41.7% of patients (n=25) were smokers, while 58.3% denied smoking. This prevalence exceeds general population smoking rates in most European samples, indicating behavioral enrichment within the psychosis cohort. Substance use is more prevalent in urban areas (1, 28). These substances may partially mediate the association between urban living and psychotic relapse (1, 28). Although cross-tabulation between smoking and hospitalization categories was not available for inferential testing, the substantial smoking burden within a relapse-prone sample suggests a potential interaction between nicotine use and illness chronicity. From a statistical standpoint, the near 42% smoking rate represents a clinically meaningful exposure cluster warranting further stratified analysis in future studies. Additionally, patients living in high-stress environments are more likely to experience daily disruptions, reduced social support, and lower treatment continuity, all of which contribute to poor adherence (6, 29). Homelessness, unstable housing, and frequent address changes common in deprived urban zones can reduce access to outpatient psychiatric care and timely follow-up as well (4, 30).

Our analysis of the scientific literature revealed several protective factors against psychotic relapse in vulnerable patients, including physical environmental resources, social buffers, and individual-level attributes. Firstly, access to green spaces has been consistently associated with lower stress levels, which results in reduced psychiatric symptom burden and improved overall mental health (4, 31). Exposure to natural environments improves cognitive restoration by enhancing attention and working memory, while reducing perceived stress (1, 31). Studies of youth show that green-space deprivation correlates with increased psychotic symptoms, illustrating the protective effect of these spaces (3, 31). Secondly, strong community cohesion has been shown to protect against the adverse mental health consequences of urban living (4, 32). Higher social capital reduces loneliness, mitigates social defeat, and increases coping capacity in vulnerable individuals (5, 32). Cultural identity and co-ethnic density also play mitigating roles with minority individuals experiencing fewer psychotic relapses when living in communities with higher ethnic representation (5, 33). Moreover, positive family environments appear to decrease stress-related cortisol responses and help prevent symptom exacerbation (3, 34). Another factor that seems to moderate the relationship between urban stress and psychotic relapses is psychological resilience (6). Cognitive-behavioral interventions have been shown to lower psychotic experiences in

high-stress environments by enhancing coping skills and reducing catastrophic thinking (3, 35, 36). Higher cognitive reserve may also moderate the impact of sensory overload and social stress via top-down neural regulation (24, 37). Social skills training, structured psychoeducation, physical activity, or mindfulness are also tied to enhanced ability to seek support during early signs of decompensation by improving stress reactivity and emotional regulation (1, 4, 36). Finally, early intervention acts as a buffer against psychotic decompensations due to urban stress, particularly for individuals with controlled psychotic symptoms (6, 36). Urban areas have a better availability of specialized psychiatric services, which can facilitate rapid treatment response (3). Coordinated specialty care (i.e. psychotherapy, family interventions, and case management) significantly reduce relapse rates in high-risk individuals (1, 36). However, disparities in service accessibility within cities mean that protective effects rely heavily on socioeconomic status and local system capacity (4).

CONCLUSIONS

Our study aimed to clarify the connection between urbanicity and the risk of psychosis and psychotic relapse in a hospital-based cohort. Urbanization exerts a significant and consistently replicated influence on the risk of psychosis, affecting both the onset and course of schizophrenia-spectrum disorders across diverse populations. Epidemiological studies demonstrate strong associations between urbanicity and increased psychotic risk, which is further supported by evidence showing that migration, minority stress, socioeconomic deprivation, and social fragmentation impact vulnerable group within cities. Moreover, mechanistic studies reveal that urban stress affects neurobiological pathways central to psychosis. These neural changes align with the patterns observed in high-risk and first-episode populations, suggesting that urbanicity functions as a meaningful environmental risk factor rather than a simple social correlate. Urban stressors additionally contribute to symptomatic destabilization and relapse among individuals with established psychosis.

At the same time, we identified several protective factors that can buffer the adverse effects of urbanicity. Policy interventions that enhance environmental quality, reduce inequality, and strengthen social infrastructure have shown promise in mitigating mental health disparities. Incorporating mental health priorities into city planning is increasingly recognized as crucial for improving urban population's quality of life.

Ultimately, future research is necessary and must integrate epidemiology with urban neuroscience, high-resolution environmental modelling, and gene-environment interaction framework to fully characterize the processes through which cities shape psychotic risk. Addressing the risk of psychotic relapse in urban areas requires coordinated interdisciplinary action across psychiatry, public health, and urban planning to transform cities into supportive, health-promoting spaces.

IMPACT OF CYSTIC FIBROSIS TRANSMEMBRANE CONDUCTANCE REGULATOR MODULATORS ON RESPIRATORY, NUTRITIONAL, AND INTESTINAL PARAMETERS IN CHILDREN WITH CYSTIC FIBROSIS: A SINGLE CENTER OBSERVATIONAL STUDY (Abstract): Highly effective cystic fibrosis transmembrane conductance regulator (CFTR) modulators have substantially changed the course of pediatric cystic fibrosis (CF) by improving CFTR function, respiratory outcomes, and nutritional status. The extent to which modulator therapy reverses severe exocrine pancreatic insufficiency and chronic low-grade intestinal inflammation in children remains incompletely defined. **Aim:** To characterize the multidimensional impact of CFTR modulator therapy on CFTR function, respiratory morbidity, nutritional status, exocrine pancreatic function, and intestinal inflammation in a real-world pediatric CF cohort. **Materials and methods:** In this prospective, single-center observational study (April 2024-January 2026), we included children aged 1-17 years with confirmed CF. The main treatment cohort comprised 32 genetically eligible children who initiated and maintained CFTR modulator therapy (ETI) for at least 12 months. Sweat chloride, anthropometric z scores, respiratory microbiology, liver function, and vitamin D status were assessed at predefined timepoints. In a digestive sub cohort of 31 treated children, fecal elastase, fecal calprotectin, and fecal neutrophil gelatinase-associated lipocalin (NGAL) were measured according to treatment duration and compared with values in 22 age matched healthy controls without digestive disease. Respiratory morbidity was evaluated from the frequency of infectious pulmonary exacerbations, airway microbiology, and lung function; spirometry was performed in children aged ≥6 years and ventilatory impairment was categorized as normal, mild, moderate, or severe. **Results:** After 12 months of CFTR modulator therapy, mean sweat chloride decreased from 114.1 to 78.3 mmol/L, indicating a marked improvement in CFTR function at cohort level. Weight for age and body mass index (BMI) z scores improved significantly, whereas height for age z scores remained essentially unchanged, consistent with a predominantly weight-driven short-term nutritional recovery. The mean annual rate of infectious pulmonary exacerbations declined from 4.72 at baseline to 0.41 at 6 months, reflecting a rapid and sustained reduction in respiratory morbidity. Diagnosis before 6 months of age was associated with a higher risk of severe exocrine pancreatic insufficiency and vitamin D deficiency, delineating an early onset, severe digestive phenotype. **Conclusions:** In children

with CF, CFTR modulator therapy confers major clinical and biological benefits in terms of CFTR function, respiratory morbidity, and weight-related nutritional recovery. However, established severe exocrine pancreatic insufficiency and persistent low-grade intestinal inflammation appear only partially reversible, suggesting that the digestive phenotype of CF is less amenable to correction once structural damage has occurred. Incorporating fecal elastase and fecal inflammatory biomarkers into routine follow-up, alongside anthropometry, respiratory outcomes, and hepatic monitoring, may enhance multidimensional disease surveillance and more precisely guide long-term nutritional and hepatodigestive management in the era of highly effective CFTR modulators. **Keywords:** CYSTIC FIBROSIS, CFTR MODULATORS, FECAL CALPROTECTIN, ELEXACAFTOR, TEZACAFTOR, IVACAFTOR, SWEAT CHLORIDE, NGAL, PANCREATIC INSUFFICIENCY.

INTRODUCTION

Cystic fibrosis (CF) remains one of the most common autosomal recessive multisystem genetic disorders in childhood. It is caused by mutations in the CFTR (cystic fibrosis transmembrane conductance regulator) gene, which impair epithelial chloride and bicarbonate transport, leading to dehydrated secretions and a complex respiratory, digestive, nutritional, and hepatopancreatic phenotype (1, 2). Over the last decade, pediatric CF care has entered a new therapeutic era with the development of CFTR modulator therapies, particularly highly effective combinations such as elexacaftor / tezacaftor / ivacaftor (ETI), which target the basic molecular defect rather than acting solely at the symptomatic level (1, 2). Current standards of care acknowledge that these therapies have profoundly changed the prognosis of CF and have required a redefinition of how clinical response, long-term monitoring, and residual disease phenotypes are evaluated in the modulator era (1).

The respiratory benefits of CFTR modulators are well established. Pivotal trials and their extensions have shown that ETI leads to marked improvement in CFTR function, reflected by a significant reduction in sweat chloride concentration, together with improved lung function, fewer pulmonary exacerbations, and better overall clinical status (2). These effects were initially demonstrated in adolescents and adults with eligible genotypes. They were subsequently confirmed in children aged 6-11 years and, more recently, in those aged 2-5 years, supporting the concept that early intervention may alter disease trajectory before irreversible structural damage is fully established (3-5). In particular, phase 3 pediatric studies of ETI have shown favorable efficacy and safety profiles, reinforcing the central role of modulator therapy in contemporary pediatric CF management (3-5).

Beyond pulmonary improvement, increasing attention has been directed toward the impact of modulators on nutritional status. Malnutrition and growth failure remain major determinants of prognosis in pediatric CF and are driven by maldigestion, chronic inflammation, recurrent respiratory infection, and increased energy expenditure (6). In the CFTR modulator era, several studies and recent reviews have consistently reported improvements in body weight and body mass index, suggesting that partial restoration of CFTR activity may reduce the metabolic burden of disease and improve nutrient utilization (3, 5, 6).

However, the magnitude of these benefits is hetero-geneous, and nutritional recovery is not uniform across all anthropometric parameters, with linear growth often responding more slowly than weight gain (6). These observations support the need for an integrated longitudinal evaluation of nutritional response under modulator therapy, particularly in children, for whom growth and developmental windows are of major clinical relevance (6).

In contrast to the robust respiratory and weight-related response, the extrapulmonary digestive benefits of CFTR modulators remain incompletely defined. The exocrine pancreas is one of the earliest and most severely affected organs in CF, and exocrine pancreatic insufficiency often develops in the first months of life (7, 8). Although emerging evidence suggests that modulator therapy may increase fecal elastase levels and allow partial recovery of pancreatic function in a small subgroup of patients, especially those treated early and with less advanced residual damage, most children with severe exocrine pancreatic insufficiency do not achieve full pancreatic sufficiency (7,8). A recent review emphasized that, although the paradigm of exocrine pancreatic disease is beginning to shift in the era of highly effective modulator therapy, meaningful functional recovery remains limited to a minority of patients, and objective monitoring with fecal elastase continues to be recommended in clinical practice (8).

Another insufficiently clarified domain is persistent intestinal inflammation in CF. A growing body of evidence supports the existence of a CF-associated enteropathy characterized by dysbiosis, altered intestinal permeability, maldigestion, and low-grade mucosal inflammation (9-11). Earlier studies demonstrated that fecal inflammatory markers, particularly fecal calprotectin, may be elevated in children with CF, and this intestinal inflammation has been associated with more severe clinical phenotypes and impaired growth (9, 10). More recent systematic reviews, however, indicate that the interpretation of fecal calprotectin in CF remains complex, as it may reflect both intestinal inflammation and a broader systemic inflammatory burden (11). In parallel, newer biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL) have attracted interest for the assessment of epithelial and neutrophil-driven inflammation, although experience in pediatric CF remains limited (12, 13). Emerging data suggest that modulator therapy may only partially improve intestinal inflammation, while complete normalization is not consistently observed, particularly in patients with longstanding or advanced digestive disease (12, 13).

In this context, real-world studies in pediatric cohorts remain essential. Clinical trials of CFTR modulators often include highly selected populations, relatively limited follow-up periods, and underrepresentation of severe or complex digestive phenotypes (2-5). In everyday clinical practice, individual response to modulator therapy is influenced by age, genotype, pre-existing pulmonary and digestive structural damage, baseline nutritional phenotype, and duration of treatment exposure (1, 6, 8). Therefore, a multidimensional evaluation of children treated with CFTR modulators-including parameters of CFTR function, respiratory morbidity, growth, exocrine pancreatic function, and fecal inflammatory biomarkers-is needed to better understand which components of disease are reversible and which persist as residual phenotypes in

the era of highly effective modulators (1, 7, 8, 12, 13).

Against this background, the present study aimed to assess the impact of CFTR modulator therapy on respiratory, nutritional, and intestinal parameters in a monocentric pediatric CF cohort under real-world conditions, integrating a longitudinal before-and-after treatment analysis with a cross-sectional comparison against healthy controls.

MATERIALS AND METHODS

We conducted a prospective, single-center observational study at a regional pediatric CF referral center between April 2024 and January 2026. The study combined a longitudinal component, assessing repeated measurements before and after CFTR modulator initiation, with a cross-sectional comparison of digestive biomarkers between children with CF and healthy controls.

Inclusion criteria: children aged 1-17 years with confirmed CF were consecutively enrolled during routine clinical follow-up. The diagnosis of CF was established based on a compatible clinical phenotype, an abnormal or intermediate sweat chloride test confirmed according to current standards, and the identification of two pathogenic or likely pathogenic CFTR variants. **Exclusion criteria** included non-CF gastrointestinal disease, known inflammatory bowel disease, malignancy, other major comorbidities unrelated to CF, and incomplete follow-up during the study period.

The main treatment cohort consisted of 32 genetically eligible children with CF who initiated and maintained CFTR modulator therapy and had available longitudinal follow-up data. A digestive sub-cohort of 31 treated children was included in the analysis of fecal biomarkers. For comparison of inflammatory and pancreatic fecal markers, 22 apparently healthy age-matched children without a history of inflammatory bowel disease, chronic malabsorption, or chronic gastrointestinal infection were enrolled as controls.

Eligible patients received CFTR modulator therapy according to national recommendations, based on age and genotype. Treatment regimens included corrector/potentiator combinations, with most children receiving elexacaftor/ tezacaftor/ ivacaftor (ETI). Dosing was adjusted for age and body weight. Participants were evaluated at baseline, before treatment initiation, and at regular follow-up visits, for at least 6-12 months for systemic outcomes, with a longer observation period available for selected digestive and hepatic parameters.

At each visit, the following variables were recorded: demographic and genetic characteristics; anthropometric data (weight, height, BMI, and corresponding age and sex adjusted z scores); respiratory outcomes (number of pulmonary exacerbations, hospitalizations, and antibiotic courses); respiratory microbiology; selected biochemical parameters (including liver enzymes and vitamin status); and sweat chloride concentration. Sweat chloride was measured using standardized procedures at baseline and after at least 12 months of CFTR modulator therapy. Infectious pulmonary exacerbations were recorded longitudinally at baseline and during follow-up and were defined in accordance with European CF working group recommendations and criteria used in recent real-world ETI studies.

Lung function was assessed by spirometry in children aged ≥6 years, in line with international and national guidelines that

recommend spirometry as the standard for objective evaluation of ventilatory function from this age, when cooperation is generally reproducible. The main parameter analyzed was forced expiratory volume in 1 second (FEV_1), expressed as a percentage of the predicted value for age, sex, and height. FEV_1 was recorded at baseline and at scheduled follow-up visits, and the severity of ventilatory impairment was categorized as normal, mild, moderate, or severe, according to current recommendations.

Fecal samples were collected from spontaneously passed stool during periods of clinical stability, in the absence of acute gastroenteritis and without recent exposure to antibiotics likely to substantially alter the intestinal microbiota. Samples were stored refrigerated, transported promptly to the laboratory, and frozen until analysis.

The following fecal biomarkers were measured: fecal elastase (µg/g) as a marker of exocrine pancreatic function; fecal calprotectin (µg/g) as a marker of intestinal inflammation; and fecal lipocalin 2/NGAL (ng/g) as an additional biomarker of mucosal inflammation and barrier dysfunction. Measurements were performed using commercially available ELISA kits validated for pediatric use, according to the manufacturers' instructions; all samples were analyzed in duplicate, and results were expressed per gram of stool.

Study Objectives. The primary objectives of the study were: (1) to assess changes in sweat chloride following initiation of CFTR modulator therapy; (2) to evaluate changes in nutritional status, as reflected by weight for age, height for age, and BMI z scores; and (3) to characterize changes over time in the frequency of infectious pulmonary exacerbations and, where available, FEV_1, given its role as a major prognostic marker in CF.

Secondary objectives were: (1) to describe fecal elastase, calprotectin, and NGAL levels in children treated with CFTR modulators; (2) to compare fecal biomarkers between children with CF and healthy controls; and (3) to explore associations between digestive biomarkers, exocrine pancreatic insufficiency, vitamin D status, respiratory profile (including FEV_1, when available), and hepatic markers.

Statistical Analysis. Statistical analyses were performed using Python (Pandas and SciPy libraries). Continuous variables were summarized as mean ± standard deviation or median and interquartile range (IQR), according to their distribution. Categorical variables were described as frequencies and percentages. Normality was assessed using the Kolmogorov-Smirnov, Anderson-Darling, D'Agostino-Pearson, and Shapiro-Wilk tests.

Paired comparisons for longitudinal outcomes were performed using paired t tests or corresponding non-parametric tests, as appropriate. Comparisons between the CF and control groups were carried out using independent samples t tests or Mann-Whitney tests, depending on data distribution. Repeated measures ANOVA was used to evaluate changes in pulmonary exacerbation frequency over time. Associations between categorical variables were analyzed using Fisher's exact test, with relative risks and 95% confidence intervals reported where relevant. A two-sided p value <0.05 was considered statistically significant.

Ethical Considerations. The study was approved by the institutional ethics committee and conducted in accordance with the Declaration of Helsinki, national regulations

governing biomedical research in minors, respectively, by the Ethics Committee of the Sf. Maria Emergency Children Hospital, Iasi (approved number 31600/26.10.2023) and by the Research Ethics Committee of the Grigore T. Popa University of Medicine and Pharmacy Iasi (approved number 434 /24.04.2024). Written informed consent was obtained from the legal guardians of all participants, and assent was additionally obtained from older children and adolescents, where appropriate. All data were anonymized before analysis.

RESULTS

Baseline Characteristics. The study included 32 children with CF treated with CFTR modulators and 22 healthy controls, who were used for digestive biomarker comparisons. The mean age at CF diagnosis in the treated cohort was 29.63 months (95% CI: 15.63-43.62), and the median age at evaluation was approximately 12 years. Most treated children carried severe CFTR variants functionally classified as class I/II, including 18 patients (56.3%) homozygous for F508del. More than half of the treated patients were diagnosed before 6 months of age, mainly in the context of abnormal newborn screening or meconium ileus. All children receiving modulators had exocrine pancreatic insufficiency, and approximately 90% had severe pancreatic insufficiency (fecal elastase <100 µg/g). At modulator initiation, 61% of patients met criteria for malnutrition. Baseline demographic and clinical characteristics of the cohorts are summarized in first table.

TABLE I.

Baseline demographic, genetic, and clinical characteristics of the study population

Variable	CF modulator group (n = 32)	Healthy controls (n = 22)
Age at evaluation, years	~12 (median)	~12 (median)
Age at diagnosis, months	29.63 (95% CI: 15.63-43.62)	
Female sex, n (%)	18 (56.3%)	**11 (50.0%)**
508del homozygous, n (%)	18 (56,3%)	-
Diagnosis before 6 months of age, n (%)	~54%	-
Exocrine pancreatic insufficiency, n (%)	32 (100%)	0
Severe EPI (fecal elastase <100 µg/g), n (%)	~90%	0
Malnutrition at treatment initiation, n (%)	61%	0

The median age at evaluation in the CF modulator group was approximately 12 years, comparable to the age range of the control group, and the sex distribution was similar (56.3% *vs.* 50% female), making a major confounding effect of these variables on subsequent comparisons unlikely. The mean age at diagnosis in the treated group was 29.63 months, although more than half of the patients were identified before 6 months of age, reflecting early diagnosis, often in the context of abnormal newborn

screening or suggestive digestive manifestations.

From a genetic standpoint, most children carried class I/II CFTR variants, and F508del homozygotes accounted for 56.3% of the cohort, indicating a mutation profile dominated by minimal function genotypes. All patients receiving modulators had exocrine pancreatic insufficiency, and approximately 90% had severe EPI (fecal elastase <100 µg/g), in contrast to the complete absence of pancreatic involvement in the control group. At treatment initiation, 61% of children with CF were malnourished, whereas none of the healthy controls met malnutrition criteria. Taken together, these data show that although the groups are comparable in terms of age and sex, the CF modulator cohort is characterized by a severe genotype, early disease onset, and a profoundly abnormal digestive phenotype with severe EPI and nutritional deficit, justifying careful assessment of the response to modulator therapy in this high-risk population.

CFTR Function and Nutritional Response to Modulator Therapy.

Changes in CFTR function, anthropometric parameters, lung function, and respiratory morbidity following initiation of CFTR modulators are summarized in second table. After 12 months of treatment, a robust pharmacodynamic response was observed, reflected by a marked reduction in sweat chloride concentration. Mean sweat chloride decreased from 114.1 mmol/L (95% CI: 105.4-122.8) at baseline to 78.3 mmol/L (95% CI: 69.8-86.8) at 12 months, corresponding to a mean change of −35.78 mmol/L (95% CI: −46.00 to −25.57; $t(31) = 7.144$; $p < 0.001$). This magnitude of response is consistent with values reported in clinical trials and real-world studies of ETI and indicates substantial correction of CFTR dysfunction at the cohort level.

Nutritional recovery during the first year of treatment was predominantly driven by weight gain. Weight for age z scores improved from −1.03 to −0.17, and BMI for age z scores from −1.01 to 0.13, with both changes being highly statistically significant ($p < 0.0001$). In contrast, height for age z scores remained virtually unchanged (−0.65 at baseline *vs.* −0.65 at 12 months; $\Delta = +0.057$ SD; $p = 0.717$), suggesting that early nutritional benefit is expressed mainly through weight restoration, whereas linear growth likely requires longer observation intervals to show detectable improvement.

In accordance with current recommendations for pediatric lung function testing, standardized spirometry was performed only in children aged ≥6 years, in whom cooperation is generally reproducible. In this subgroup with spirometry available at 12 months, mean FEV_1 increased from 62.4% to 77.4% of the predicted value, corresponding to a mean gain of 14.9 percentage points (95% CI: 8.5-21.3; $p = 0.0001$). This improvement in $ppFEV_1$ falls within the range of increases reported in clinical and observational ETI studies in children and adolescents (approximately 9-14 percentage points) and confirms that, in our pediatric cohort, modulator therapy is associated with a substantial functional gain in lung function.

In parallel, the mean number of infectious pulmonary exacerbations declined from 4.72 episodes per year at baseline to 0.41 episodes during the first 6 months of treatment, a reduction that was highly statistically significant ($p<0.0001$). The

concomitant decrease in sweat chloride, improvement in weight-related z scores, increase in ppFEV$_1$, and abrupt fall in exacerbation frequency support a major and rapid impact of CFTR modulators on CFTR function, nutritional status, and respiratory morbidity. Overall, under real-world conditions, CFTR modulator therapy in children with CF is associated with a rapid and clinically meaningful improvement in CFTR function, a substantial correction of weight deficit, and a relevant enhancement of lung function, whereas the trajectory of statural growth appears, at least in the short term, to be less clearly influenced.

TABLE II.
Changes in CFTR function, anthropometry, and respiratory outcomes following CFTR modulator therapy.

Outcome	Baseline	Follow-up	Effect estimate	p value
Sweat chloride (mmol/L)	114.1	78.3 at 12 months	−35.78 mmol/L (95% CI: −46.00 to −25.57)	<0.001
Weight-for-age z-score	−1.03	−0.17 at 12 months	+0.86 SD	<0.0001
BMI-for-age z-score	−1.01	0.13 at 12 months	+1.06 SD equivalent	<0.0001
Height-for-age z-score	−0.65 SD	−0.65 SD	+0.057 SD	0.717
Infectious pulmonary exacerbations	4.72/yr.	0.41 at 6 months	Marked reduction over time	<0.0001
pp FEV$_1$ % predicted	62.4 %	77.4 at 12 months	+14.9 percentage points (95% CI: +8.5 to +21.3)	p= 0.0001

*ppFEV$_1$ calculated in the subgroup of 20 children aged ≥6 years with complete FEV$_0$-FEV$_{12}$ data

Respiratory Parameters and Microbiological Profile. Changes in respiratory morbidity after initiation of CFTR modulator therapy are detailed in Table 2 and in this subsection. Infectious pulmonary exacerbations showed an abrupt reduction during the first 6 months of treatment, with the mean number of episodes decreasing from 4.72 ± 1.20 episodes per year at baseline (95% CI: 4.29-5.15) to 0.41 ± 0.76 episodes in the first 6 months (95% CI: 0.13-0.68; $p < 0.0001$). Repeated measures ANOVA (timepoints: baseline, 1, 3, and 6 months) demonstrated a highly significant overall effect of time on exacerbation frequency (Greenhouse - Geisser corrected $F(1.692, 52.44) = 140.7$; $p < 0.0001$), indicating a strong and sustained therapeutic impact of modulators on respiratory morbidity.

Trend analysis suggested a predominantly linear downward pattern, with a rapid decline in exacerbations immediately after treatment initiation and subsequent stabilization at very low values. This profile is consistent with real-world ETI data in adolescents and adults and confirms the major early impact of modulator therapy on exacerbation burden in the pediatric population. Together with the increase in ppFEV$_1$ and improvement in nutritional parameters, these findings support an im-

portant overall respiratory benefit in the cohort analyzed.

Concerning respiratory microbiology, chronic colonization with *Pseudomonas aeruginosa* and/or *Staphylococcus aureus* showed clinically plausible associations with disease severity and bronchiectasis burden; however, these relationships did not reach statistical significance in the present cohort, likely due to the relatively small sample size and limited number of events. Nevertheless, the observed trends are consistent with our previous data demonstrating a correlation between *S. aureus* and *P. aeruginosa* colonization and bronchiectasis development in the extended center cohort, suggesting that the microbiological profile remains an important determinant of respiratory severity even in the modulator era.

Exocrine Pancreatic Function and Intestinal Inflammation. The profile of digestive biomarkers in children with CF treated with CFTR modulators and in healthy controls is presented in table III. Compared with healthy controls, children with CF on modulator therapy had significantly higher levels of fecal inflammatory biomarkers. Median fecal calprotectin was 92.4 µg/g (IQR: 30.7-196) in the CF group versus 18.8 µg/g (IQR: 5-40) in controls ($p = 0.0028$), with approximately half of the CF children having values above 100 µg/g. Median fecal NGAL was also higher in children with CF than in controls (1.685 µg/g *vs.* 0.915 µg/g; $p = 0.0008$), whereas values in the control group were often very low or undetectable.

Fecal elastase remained profoundly reduced in the CF cohort, with a median value of 1.2 µg/g (IQR: 0.5-20), while all controls had values ≥200 µg/g ($p < 0.0001$). This confirms the persistence of severe exocrine pancreatic insufficiency despite exposure to highly effective modulator therapy, in contrast to isolated reports of partial pancreatic function recovery in a small subset of patients.

Longitudinally, neither fecal calprotectin nor fecal NGAL showed a clear trend towards normalization under treatment. Median calprotectin values remained broadly similar across exposure categories (approximately 108 µg/g at 0-12 months, 69 µg/g at 12-24 months, and 91 µg/g at >24 months; $p = 0.73$), and fecal NGAL exhibited a similar pattern ($p = 0.72$). Although several individual patients demonstrated decreases in calprotectin over time, none achieved complete normalization below 50 µg/g, suggesting the persistence of concomitant low-grade intestinal inflammation in most children, in line with published data on CF-associated enteropathy.

Exocrine pancreatic function also remained essentially unchanged over the course of longitudinal follow-up. Fecal elastase values remained below 100 µg/g in almost all patients, and no child reached the threshold for pancreatic sufficiency (>200 µg/g); only one patient shifted from severe to moderate exocrine pancreatic insufficiency. Fecal calprotectin and NGAL correlated positively with each other and inversely with fecal elastase, supporting the presence of a persistent digestive phenotype characterized by low-grade intestinal inflammation and severe exocrine pancreatic insufficiency. Figures 1-3 graphically illustrate these between-group differences and the inter-individual variability of fecal biomarkers, liver function, and intestinal inflammation in CF patients treated with modulators.

TABLE III.

Digestive biomarker profile in children with CF treated with CFTR modulators and in healthy controls.

Biomarker	CF group	Healthy controls	p value
Fecal calprotectin (µg/g)	92.4 (IQR: 30.7-196)	18.8 (IQR: 5-40)	0.0028
Fecal NGAL (µg/g)	1.685	0.915	0.0008
Fecal elastase (µg/g)	1.2 (IQR: 0.5-20)	≥200 in all controls	<0.0001

Vitamin D and Hepatic Profile

The evolution of hepatic parameters during CFTR modulator therapy is presented in table IV. Children diagnosed before 6 months of age had a significantly higher risk of severe exocrine pancreatic insufficiency and vitamin D deficiency, suggesting that an early and severe digestive phenotype is closely linked to minimal function CFTR genotypes and early pancreatic involvement.

Under CFTR modulator therapy, the hepatic profile remained globally stable, with only modest and transient changes in liver enzymes. Median ALT increased slightly at 6 months, followed by a decline to values below baseline after more than 24 months (29.3 (23.1-41.4) U/L at baseline *vs.* 24.9 (21.5-30.5) U/L at >24 months; p = 0.009), with a similar pattern observed for AST (28.2 (21.8-38.3) U/L at baseline *vs.* 22.8 (19.4-28.5) U/L at >24 months; p = 0.006). GGT, total bilirubin, and INR remained stable and within normal limits throughout follow-up, in line with studies reporting minimal or no hepatic changes under ETI.

No significant correlations were identified between peak ALT values and fecal calprotectin or NGAL levels, suggesting that mild variations in transaminases were largely independent of intestinal inflammatory burden. However, all cases of mild hepatic abnormalities occurred in children with severe exocrine pancreatic insufficiency and severe CFTR genotypes, whereas no child with residual pancreatic function exhibited hepatic changes, supporting a close relationship between a severe digestive phenotype and hepatic vulnerability.

TABLE IV.

Evolution of hepatic parameters during CFTR modulator therapy.

Parameter	Baseline median (IQR)	6-month median (IQR)	>24-month median (IQR)	p-value (baseline *vs.* >24 months)
ALT (U/L)	29.3 (23.1-41.4)	35.6 (23.8-45.0)	24.9 (21.5-30.5)	0.009
AST (U/L)	28.2 (21.8-38.3)	34.6 (20.4-42.3)	22.8 (19.4-28.5)	0.006
GGT (U/L)	17.4 (15.2-22.5)	18.0 (15.0-25.0)	18.2 (15.2-21.5)	0.270
Total bilirubin (mg/dL)	0.51 (0.36-0.63)	0.50 (0.40-0.70)	0.54 (0.39-0.64)	0.920
INR	1.02 (0.98-1.03)	1.01 (0.99-1.04)	1.01 (0.98-1.04)	0.150

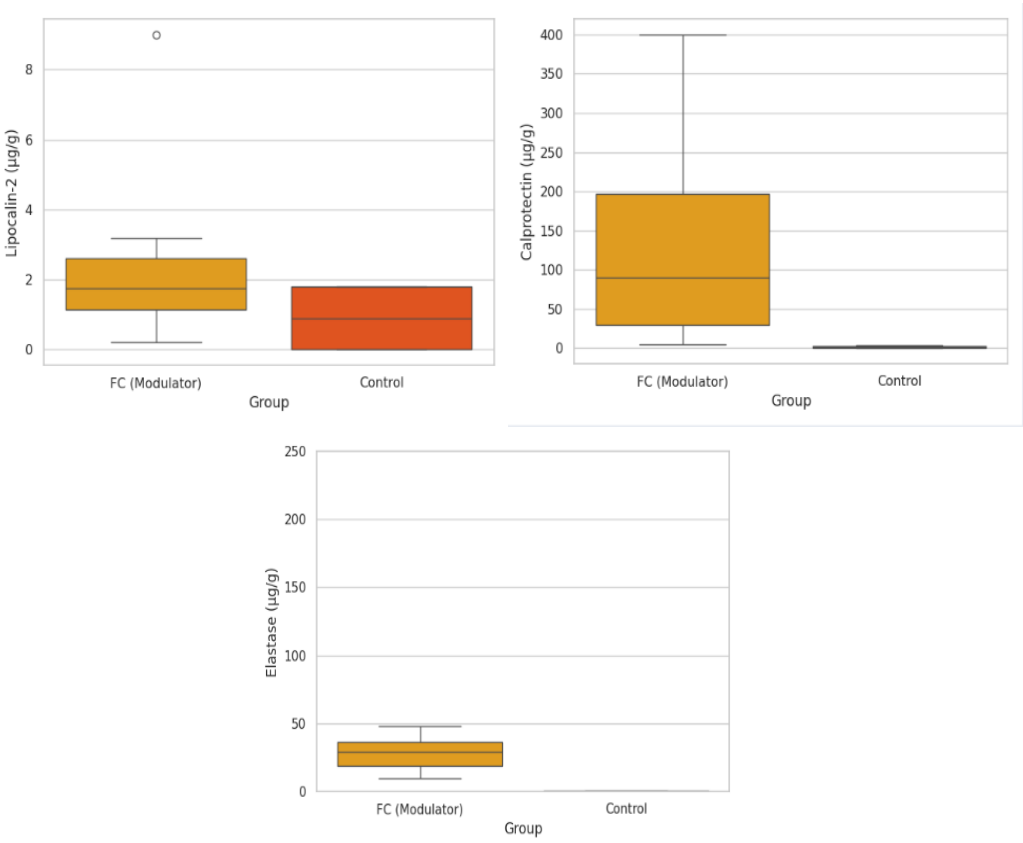

Fig. 1. Fecal digestive biomarkers in children with CF receiving CFTR modulator therapy compared with healthy controls.

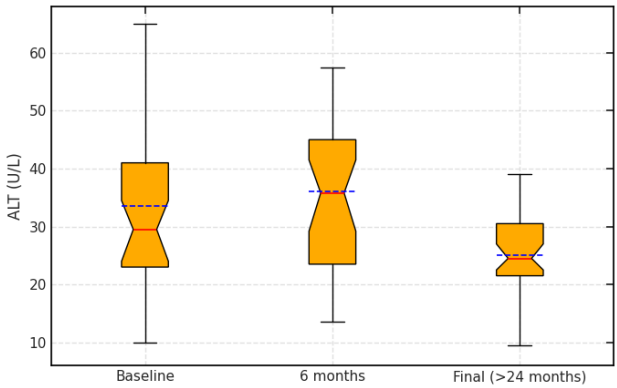

Fig. 2. ALT evolution at baseline, 6 months, and >24 months of CFTR modulator therapy, illustrating a transient increase at 6 months followed by a decline below baseline values ($p < 0.01$), suggestive of a modest improvement in hepatic profile.

DISCUSSION

This pediatric real-world study shows that CFTR modulator therapy elicits a strong, yet organ-specific, therapeutic response in children with cystic fibrosis. The most pronounced benefits were observed in CFTR function, respiratory morbidity, and weight-related nutritional recovery, whereas severe exocrine pancreatic dysfunction and low-grade intestinal inflammation were only minimally reversible in most patients, which is consistent with other studies in the literature. (7, 8, 12, 14).

The marked reduction in sweat chloride confirms a robust pharmacodynamic effect of CFTR modulators under routine clinical conditions. Although the magnitude of sweat chloride decline in this cohort was somewhat lower than that reported in tightly selected pediatric ETI trials, the change remained clinically meaningful and likely reflects real-world heterogeneity in genotype, baseline disease severity, preexisting structural damage, and treatment adherence (2-5, 14, 15). Similar variability has been reported in observational studies, in which a substantial proportion of ETI-treated patients retain sweat chloride values above 60 mmol/L despite overall improvement, underscoring that CFTR correction is heterogeneous outside trial settings (14-16). Collectively, these findings support the role of sweat chloride as a useful, but not fully deterministic, biomarker of treatment response in the modulator era.

Respiratory improvement in our cohort was substantial. The abrupt decline in infectious pulmonary exacerbations during the first six months of therapy supports the concept that highly effective modulators interrupt the cycle of mucus obstruction, infection, and inflammation that drives CF lung disease progression (2-5, 14). This pattern is consistent with observational cohorts and registry data showing marked reductions in pulmonary morbidity after the introduction of ETI, including fewer exacerbations, hospitalizations, and antibiotic courses (3-5, 14, 15). The gain in ppFEV$_1$ in the subgroup with spirometry data was also in line with real-world pediatric series, which report meaningful improvements in lung function sustained over 12 months and beyond (3-5, 14-16). Nevertheless, persistent chronic airway colonization in some children indicates that established infection

and bronchiectatic structural lung disease are not fully reversible through CFTR correction alone, and that airway microbiology remains an important determinant of long-term respiratory outcomes (14-16).

From a nutritional standpoint, treatment was associated with substantial improvements in weight and BMI for age z scores, whereas height for age remained essentially unchanged during the first year of follow-up. This dissociation suggests that improved energy balance and reduced inflammatory burden may drive early weight catch-up, while linear growth likely requires longer follow-up and may remain constrained by prior disease burden, long-standing exocrine pancreatic insufficiency, and cumulative nutritional deficits. A similar early divergence between weight and height trajectories has been reported in longitudinal registry analyses, including recent Danish data showing that height z scores remained largely unchanged two years after ETI initiation despite significant gains in weight and BMI (17). These observations support the notion that statural deficits represent a more fixed component of the CF phenotype once established and may not fully normalize even in the context of highly effective CFTR modulation.

The digestive findings are among the most clinically relevant aspects of this study. Severe exocrine pancreatic insufficiency persisted in nearly all children despite modulator exposure, and there was no meaningful recovery of fecal elastase in the vast majority of patients. This observation supports the concept that, once acinar destruction and fibrosis are established, restoration of epithelial ion transport alone is insufficient to reestablish exocrine pancreatic function. (18) Reports of pancreatic recovery under CFTR modulators have been largely confined to infants and very young children treated early, before advanced structural damage is present. For example, extension data from ivacaftor trials in children aged 2-5 years showed sustained improvements in fecal elastase, suggesting that early modulation may delay or mitigate pancreatic deterioration in selected genotypes (18-20). In older patients with established structural disease-such as our cohort with a median age of 12 years-exposure to elexacaftor/tezacaftor/ivacaftor appears insufficient to restore exocrine function, in line with PROMISE GI findings showing no clinically significant change in fecal elastase after six months of ETI in patients aged ≥12 years (18-21).

Similarly, fecal calprotectin and NGAL remained elevated compared with healthy controls and did not normalize over time, despite an excellent respiratory and weight response. In line with previous work, fecal calprotectin levels in children with cystic fibrosis are frequently above normal and often reflect overall disease burden rather than overt gastrointestinal symptoms (22). The inverse relationship between fecal inflammatory markers and fecal elastase in our cohort suggests that severe exocrine pancreatic insufficiency and intestinal inflammation may represent interconnected components of a common digestive phenotype rather than independent abnormalities (18, 20). Prospective multicenter data show that CFTR modulators reduce intestinal inflammation, with a significant fall in fecal calprotectin-particularly under elexacaftor / tezacaftor/ ivacaftor-yet a substantial proportion of patients retain abnormal values after 6-12 months of treatment, indicating only partial resolution of CF-associated enteropathy (12).

The pattern of liver enzyme dynamics

observed in this cohort - a modest early increase followed by longer-term normalization - is consistent with emerging evidence on the hepatic effects of elexacaftor/tezacaftor/ivacaftor. In pediatric cohorts evaluated with shear wave or transient elastography, initiation of elexacaftor/tezacaftor/ivacaftor has been associated with mild, mostly transient elevations in transaminases and a subsequent reduction in liver stiffness among children with cystic fibrosis and hepatobiliary involvement (23). In our study, GGT, total bilirubin, and INR remained stable and within normal limits, and late ALT and AST values fell below baseline, supporting a favorable hepatic safety profile overall that is in line with systematic reviews of CFTR modulator therapies and their impact on liver biochemistry and non-invasive liver disease markers (24). Persistence of vitamin D deficiency in children with severe exocrine pancreatic insufficiency further underscores that CFTR modulators do not eliminate the need for structured digestive and hepatobiliary management. Pancreatic enzyme replacement, supplementation with fat-soluble vitamins, and close nutritional and hepatic monitoring should therefore not be relaxed solely based on respiratory or anthropometric improvement (24).

This study has several strengths. It prospectively evaluates a real-world pediatric cohort, integrates systemic and digestive outcomes, incorporates healthy controls for fecal biomarker comparison, and addresses a clinically relevant but insufficiently explored question: whether highly effective CFTR modulators fully reverse the digestive phenotype of CF. However, several limitations must be acknowledged. The study was single-center and included a modest sample size, limiting statistical power for subgroup analyses, and the number of untreated CF comparators was too small to support robust parallel inferences. Follow up duration varied across outcomes, and some analyses were restricted to subgroups with available longitudinal digestive data. In addition, the observational design precludes causal inference, and the study did not include microbiome sequencing or standardized imaging of structural gastrointestinal disease.

Despite these limitations, the present findings have important clinical implications. In pediatric CF, treatment success should not be defined solely by improved respiratory outcomes and weight gain. The persistent burden of digestive disease remains clinically relevant and warrants dedicated longitudinal evaluation. A multidimensional follow-up model incorporating fecal elastase, fecal inflammatory biomarkers, vitamin status, and hepatic surveillance, alongside respiratory outcomes, may better capture overall disease activity in the era of highly effective CFTR modulators and support more precise long-term nutritional and hepato-digestive management strategies.

Future research directions. The introduction of highly effective CFTR modulators has fundamentally altered the natural history of cystic fibrosis, transforming the prognosis of pediatric patients from one defined by progressive functional decline into an on-treatment prognosis that is conditioned by the degree of individual response and the magnitude of residual risk. Building on the observations from this study, several priority avenues for future research emerge.

The persistence of exocrine pancreatic insufficiency and intestinal inflammation,

reflected by elevated fecal calprotectin and NGAL, indicates that CF-associated enteropathy is not fully reversible in patients with established structural lesions (12, 16-18)/ Future studies should incorporate longitudinal fecal microbiome sequencing to elucidate the mechanisms underlying persistent dysbiosis and its relationship with intestinal inflammation in the modulator era. In parallel, prospective cohorts of infants diagnosed through newborn screening are needed to determine whether ultra-early initiation of CFTR modulators can prevent the development of this residual digestive phenotype and avert irreversible pancreatic acinar destruction (12, 18, 19-22).

Although the rapid recovery of weight and BMI for age z scores represents a major therapeutic success, this accelerated trajectory requires a re-evaluation of traditional nutritional strategies. The shift from a historical risk of undernutrition to an emerging phenotype characterized by a risk of overweight and obesity warrants detailed investigation, including the potential long-term cardiometabolic consequences. Future research should therefore longitudinally assess body composition (lean mass versus fat mass), lipid profile, and the risk of cystic fibrosis-related diabetes (CFRD), to tailor enzyme replacement, caloric intake, and dietary counselling to the new treatment-induced metabolic trajectories (17).

The mild and transient fluctuations in liver enzymes (ALT/AST) observed under elexacaftor/tezacaftor/ivacaftor in this cohort underscore the importance of rigorous pharmacovigilance. Future studies should correlate serum biomarkers (e.g., APRI) with noninvasive structural assessments such as transient elastography (Fibro Scan) to differentiate drug-related hepatotoxicity from progression of CF-associated liver disease and to define evidence-based surveillance protocols. In the same long-term safety domain, further work is needed to standardize baseline and follow-up ophthalmologic assessment in children treated with CFTR modulators, in light of pediatric reports of cataract development following early ivacaftor or ETI exposure in utero and during breastfeeding (23-26).

As respiratory morbidity, particularly pulmonary exacerbations, declines dramatically under modulator therapy, classical endpoints progressively lose their ability to discriminate long-term prognosis (23, 24, 27). Future research should validate dynamic prognostic models that integrate sensitive functional markers of small airway disease, such as the Lung Clearance Index, together with high-resolution imaging scores (e.g. chest CT bronchiectasis and air-trapping indices) (24, 26). Such a multidimensional approach may unmask silent structural lung disease and the persistence of niche chronic infections, thereby guiding individualized treatment decisions under real-world conditions, from the newborn period until adulthood (24, 26-29).

CONCLUSIONS

In this real-world pediatric cohort, CFTR modulator therapy was associated with marked clinical benefits, including substantial reductions in sweat chloride, infectious pulmonary exacerbations, and improvements in ppFEV$_1$ and weight/BMI-for-age z scores, indicating a rapid shift from progressive functional decline toward improved respiratory stability and nutritional recovery. However, severe exocrine pancreatic insufficiency and low-grade intestinal inflammation persisted in almost all children, with fecal elastase remaining profoundly reduced and fecal calprotectin

and NGAL only minimally improved, suggesting that the digestive phenotype of cystic fibrosis is only partially reversible once structural damage has occurred. The hepatic profile with elexacaftor/tezacaftor/ivacaftor was generally favorable, with only mild, transient ALT/AST elevations and stable GGT, bilirubin, and INR. Yet, enzyme fluctuations in children with severe exocrine pancreatic insufficiency and high-risk genotypes underscore the need for ongoing hepatobiliary surveillance. Overall, pediatric cystic fibrosis care in the modulator era should be judged not solely by gains in lung function or weight, but by sustained, multidimensional control of respiratory, pancreatic, intestinal, hepatic, and nutritional health across the life course, supported by early initiation of CFTR modulators and lifelong, multidisciplinary follow-up.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest.

REDUCTION OF SUBJECTIVE STRESS PERCEPTION IN FEMALE PATIENTS WITH AUTOIMMUNE HYPOTHYROIDISM AFTER RESTORING EUTHYTOID STATUS WITH LEVOTHYROXINE TREATMENT (Abstract): Autoimmune Thyroid Diseases (AITDs), comprising Graves' Disease and Hashimoto's Thyroiditis have a multifactorial origin and stress, as an environmental trigger, has been incriminated as the most frequent risk factor for the development of mood disorders. Also, hypothyroidism in Hashimoto's Thyroiditis is associated with different neuro-psychiatric conditions such as concentration, memory and attention deficits, depressive mood and anxiety disorder, particularly in the female sex. **Aim:** to evaluate the subjective perception of stress in women with newly diagnosed autoimmune hypothyroidism and the influence on stress perception of restoring euthyroidism with levothyroxine (LT_4) treatment. **Materials and methods:** we conducted a prospective study over a one-year period (October 2014 - September 2015) that included 17 female patients newly diagnosed with autoimmune hypothyroidism, with no history of psychiatric disorders or treatments and no other major ailments. Perceived stress was measured using four standardized questionnaires before and after instituting LT_4 therapy. **Results:** All patients included in our study, with a mean age of 43.8 ± 10.8, reported a stress level in the medium range. After LT_4 replacement treatment was initiated and euthyroidism was restored, subjective stress levels measured with all four questionnaires were lower compared to baseline. Furthermore, when we divided patients into subgroups, based on their reproductive status, psychometric scores of patients in the reproductively active subgroup before and after LT_4 treatment, were significantly lower after restauration of euthyroidism, but no significant reductions were observed in the menopausal subgroup. **Conclusions:** further research is needed, using more objective stress measurement methods, for a more reliable determination of the impact of LT_4 treatment and restauration of the euthyroid state in patients with autoimmune thyroid dysfunction. **Keywords**: AUTOIMMUNE THYROID DISEASE, STRESS PERCEPTION, PSYCHOMETRIC.

The spectrum of autoimmune thyroid disease (AITD) comprises two main disorders, Graves' disease (GD) and Hashimoto's Thyroiditis (HT). Although GD and HT represent two very different clinical phenotypes, they are both characterized by a dis-

ruption in the immune tolerance and an aberrant attack of the host through formation of antibodies that trigger thyroid antigens: thyroperoxidase (TPO), thyroglobulin (Tg) and thyroid stimulating hormone-receptor (TSH-R). This is histologically translated through the infiltration of the thyroid gland by B and T lymphocytes (1).

Even though the exact mechanisms behind AITD are not yet fully understood, its origin is multifactorial, environmental triggers acting on a specific genetic background (2, 3). AITDs are the leading cause of thyroid dysfunction, particularly in the modern countries, after the implementation of salt iodination programs (4). Taken together, AITDs have a prevalence that exceeds 5% in the general population and an even higher prevalence in women (5). AITDs are commonly associated with other autoimmune disorders, forming various phenotypes of the polyglandular autoimmune syndrome, which is also more prevalent in the female sex, over 85% of patients being women (6, 7, 8).

In recent years, the key role of stress (particularly psycho-social stress, psychological trauma and daily hassles) as an environmental trigger in the physiopathology of AITD has been the central subject for several studies (9, 10). There is accumulating evidence in the literature of a connection between stress and emotion-based pathologies and AITD, possibly through immunologic mechanisms and the activation of the two major axes involved in the pathophysiology of stress, the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic adreno-medullary system (SAM) (11, 12). Numerous studies have already shown that patients with GD reported significantly more stressful and negative life events than controls in the months anterior to the onset of symptoms (13) and an increase of GD incidence during or after wartime (14). In contrast to the considerable information published on the association between stress and the onset of GD, there have been fewer studies about the relationship between stressful events and HT and the results seem to be contradictory (9, 15).

Stress has also been incriminated as the most frequent risk factor for the development of mood disorders such as major depressive disorder (16) and hypothyroidism in HT is associated with different neuropsychiatric conditions such as concentration, memory and attention deficits, depressive mood and anxiety disorder (16). Also, evidence shows that female sex has a higher susceptibility to stress and ailments related to an emotional imbalance, as well as the fact that AITDs are 5 to 10 times more common in women (5). Accordingly, the aim of this study was to evaluate the subjective perception of stress in women with newly diagnosed autoimmune hypothyroidism and the influence on stress perception of restauration of the euthyroid status after levothyroxine (LT_4) treatment.

MATERIALS AND METHODS

This prospective study was conducted over a one-year period between October 2014 and September 2015 in the Endocrinology Clinic of the „Saint Spiridon" County Hospital in Iași, Romania. The experimental protocol, in conformity with the international ethical standards and was formally approved by the Local Ethics Committee (Protocol number 14,750 in July 17th2014). All subjects were recruited among patients visiting the Endocrinology Clinic diagnosed *de novo* with autoimmune hypothyroidism and provided written consent before the start of the study.

Patients were selected to participate in the study based on the following inclusion

criteria: female, 18 to 65 years old, non-obese (body mass index, BMI=18.5-29.9 kg/m^2), no history of psychiatric diagnoses and treatments, no other significant illnesses and newly diagnosed with autoimmune hypothyroidism based on positive serum thyroid antibodies (TPO and/or Tg, with a cut-off value of 40 IU/ml for both) and high thyroid stimulating hormone (TSH), as measured by a chemiluminescent method ("Sf. Spiridon" Clinical Emergency Hospital Iasi, Romania), with normal values ranging from 0.4-4.0 μIU/ml. Males, patients who were already diagnosed with thyroid dysfunction or thyroid cancer or had a partial or total thyroidectomy, patients with documented depression-anxiety disorders or who were taking antidepressive or anxiolytic medications, as well as noncooperative patients were excluded. For this study, we also excluded patients with AITD who were hyperthyroid or euthyroid.

Stress perception was evaluated in our patients by four standardized questionnaires. These questionnaires were self-administered before the clinical examination, but the investigators checked the degree of completion and interviewed patients on the missing information, without forcing answers from them. Depressive and/or anxiety symptoms was assessed using the Hamilton depression (HAM-D) and Hamilton Anxiety (HAM-A) scales. The Perceived Stress Scale (PSS) was used to measure the individual subjective stress perception scores in the study population by testing, on a scale from 1 to 5, how unpredictable patients view their lives and the extent to which they feel they can control the small challenges they face daily. The 51-items Daily Hassles (DH) scale was administered to evaluate patients' perception of stress regarding daily demands at home, at work, in their social or personal lives.

All patients were prescribed levothyroxine (LT_4) in the appropriate dosage and were called for reevaluation in 6-8 weeks. When the thyroid function normalized under LT_4 treatment, patients received again the four psychometric questionnaires.

The descriptive data are presented as means and standard deviation (SD). Statistical analysis was performed using Sigma Plot 11 (Systat Software Inc., San Jose, California) and *SPSS v.20* for Windows (SPSS Inc., Chicago, Illinois). Comparisons of numerical variables before and after LT_4 treatment were made using a paired Student's t-test. Statistical significance was set at $p < 0.05$.

RESULTS

After applying inclusion and exclusion criteria, 17 newly diagnosed patients with autoimmune hypothyroidism have agreed to participate in our survey. The characteristics of the study population are presented in table I.

TABLE I.

General and biochemical characteristics of the study population (n=17)

Age (years)	43.8 ± 10.8
BMI (kg/m^2)	26.6 ± 5.1
Smoker (n/%)	3 (0.51%)
Sleep pattern (hours/night)	7.2 ± 1.2
Physical activity (min/day)	58.8 ± 65.3
TSH (μIU/ml)	10.9 ± 11.2
Thyroid volume	10.9 ± 5.3

Data are expressed as the mean ± SD.

The study group interviews conducted at enrollment, when patients were in the hypothyroid state, showed a stress level in the medium range as measured with both PSS and DH questionnaires and the Hamilton scales for depression and anxiety showed mild depression, but no anxiety disorder. After LT_4 replacement treatment was initiated and euthyroidism was restored, subjective stress levels measured with the PSS questionnaire were significantly lower (p=0.046) compared to baseline (fig. 1). The scores for DH, HAM-D and HAM-A questionnaires were also reduced in the euthyroid state, on LT_4 therapy, compared to baseline, however, not statistically significant (p=0.79, p=0.190, p=0.397, respectively).

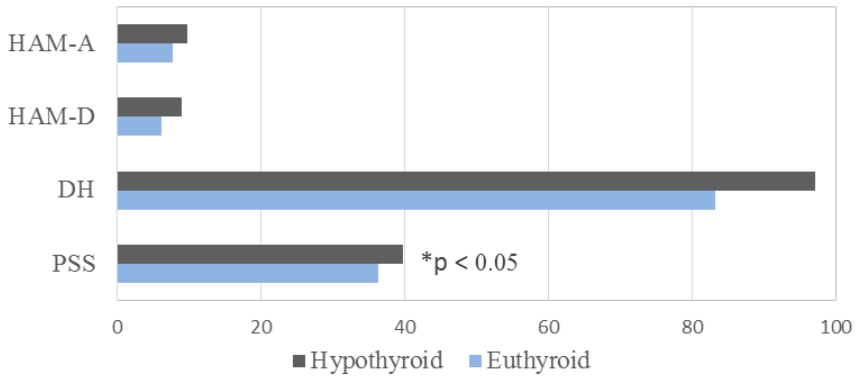

Fig. 1. Psychometric scores of the study group before and after LT_4 treatment

We divided the study group into two smaller, more homogenous subgroups: reproductively active women (n=10), with a mean age of 37.6 ± 8 and menopausal women (n=7), with a mean age of 52.7 ± 7.7. When we compared psychometric scores of patients in the reproductively active group before and after LT_4 treatment, we found a significant reduction in the scores of all four scales after restauration of euthyroidism with LT_4 therapy (tab. II).

In the menopausal subgroup, however, patients had only minimal reductions in stress levels as measured by the PSS and DH questionnaires (p=0.82 and p=0.99, respectively), while they reported an increase in Hamilton depression and anxiety scale scores (tab. III). These results were not statistically significant (p=0.38 and p=0.12, respectively).

TABLE II

Psychometric scores in women of reproductive age before and after LT_4 treatment

	Before LT_4 treatment	After LT_4 treatment	*p*
PSS	37.9 ± 8.2	32.9 ± 5.0	0.031
DH	101.4 ± 32.5	78.3 ± 8.3	0.035
HAM-D	9.0 ± 7.2	3.3 ± 2.3	0.039
HAM-A	10.6 ± 8.3	5.0 ± 1.9	0.056

Data are expressed as the mean ± SD.

TABLE III

Psychometric scores in menopausal women before and after LT_4 treatment

	Before LT_4 treatment	After LT_4 treatment	*p*
PSS	42.3 ± 6.1	41.9 ± 5.1	0.82
DH	91.1 ± 28.6	91.3 ± 19.8	0.99
HAM-D	9.0 ± 5.9	11.0 ± 6.1	0.38
HAM-A	8.4 ± 6.9	12.1 ± 1.9	0.12

Data are expressed as the mean ± SD.

When we compared psychometric scores of the two subgroups, while there were no significant differences between women in the reproductively active and the menopausal subgroups in any of the four questionnaires administered at enrollment, before the LT_4 therapy was instituted (fig. 2), after restoring the euthyroid status, during LT_4 treatment, women of reproductive age had significantly lower scores in PSS, HAM-D and HAM-A scales (p=0.034, p=0.042 and p=0.049, respectively) and a lower stress levels, however statistically non-significant (p=0.227) as measured with the DH questionnaire (fig. 3).

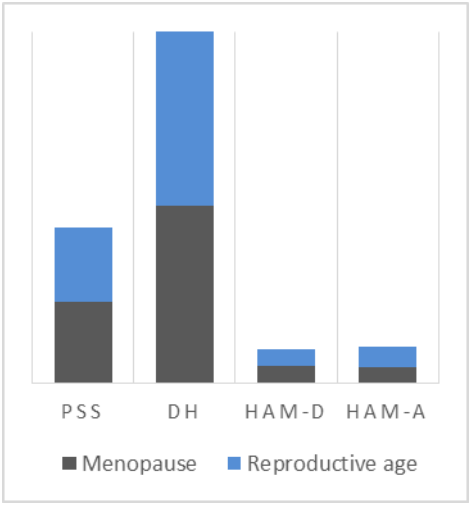

Fig. 2. Psychometric scores of subgroups before LT_4 treatment (hypothyroid state).

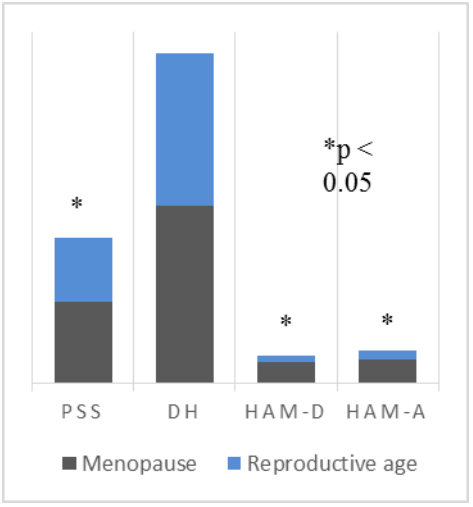

Fig. 3. Psychometric scores of subgroups during LT_4 treatment (euthyroid state).

DISCUSSION

In this report, we evaluated the impact of LT_4 treatment and restoration of the euthyroid status on the subjective perception of stress in a naïve population of women with autoimmune hypothyroidism and no history of psychiatric illnesses or other significant ailments, using four standardized questionnaires.

Stress is a key factor incriminated in the onset of various chronic conditions, as part of modern lifestyle (11). In consequence, we were not surprised that the female population included in this study reported stress perception scores in the medium range and mild depressive disorder.

As we mentioned in a previous systematic review article (10), there is a very small number of studies that evaluated the impact of stress on the onset and propagation of HT, particularly in female patients, although it is already well known that AITDs, as well as other autoimmune disorders, are caused by emotional imbalances and stress and that the prevalence of these conditions is higher in this population group.

Our main finding was that stress was perceived differently by reproductively active subjects compared to the menopausal patients in our study. It is noteworthy the fact that while in the menopausal subgroup there are no significant differences between scores of PSS and DH questionnaires before and after the administration of LT_4 treatment, in the subgroup of women of reproductive age we observed that after the restoration of euthyroidism with LT_4 therapy, the mean scores regarding subjective stress perception and general wellbeing were significantly improved. Furthermore, this research showed that in reproductively active female patients the correction of autoimmune hypothyroidism also reduces depressive and anxiety symptoms that patients reported in the hypothyroid state. In contrast, in the menopausal subgroup, depressive mood and anxiety scores tended to worsen after patients achieved euthyroidism.

We could argue that menopausal women have a more advanced age compared to reproductively active patients and they tend to have a higher risk of developing other conditions such as cardiovascular problems, which could lead patients to perceive differently daily events compared to young, healthy women (17).

Our study has some limitations. First, the small sample size may not be representative for the general population, although we tried to include only patients with no significant pathologies and no history of psychiatric disease or treatments. Another major limitation, as for every interview-based report, is recall-bias that stands from data reported from patients' memories, that is also subjective to the patients' mood in the moment of the interview.

CONCLUSIONS

The results of our study showed that female patients with autoimmune hypothyroidism have a medium stress level and there is a tendency of a reduction in the subjective stress perception after restoration of euthyroidism with LT_4 treatment in patients of reproductive age, but not in menopausal women.

We consider of essential importance the use of objective stress measurement methods, for a more reliable determination of the impact of LT_4 treatment and restauration of the euthyroid state in patients with autoimmune thyroid dysfunction.

IMAGE RECONSTRUCTION IN CARDIAC SPECT IMAGE PROCESSING (Abstract): **Aim:** The purpose of this study was to assess the effects of two reconstruction techniques of myocardial perfusion images (MPI) in cardiac patients considered at low risk for myocardial perfusion abnormalities. **Materials and methods**: We evaluated 36 patients (10 males, 26 females; median age 61 years) with rest MPI studies by comparing their myocardial SPECT images reconstructed using two different algorithms. All patients underwent myocardial SPECT imaging with 99m Tc Tetrofosmin at rest, using a Symbia Evo Excel SPECT or a Siemens e.cam dual head system. SPECT images were reconstructed using filtered back projection method, and an iterative reconstruction method using the 3D Flash algorithm. For the quantitative evaluation of the reconstructed images by two methods, the contrast, contrast to noise ratio and signal to noise ratio were calculated. Using a standard template of coronary artery distribution and the polar map displays, the summed rest scores (SRS) were calculated according to the standard coronary artery distribution. **Results:** 3D Flash reconstruction algorithm significantly increases image contrast by 31% ($p < 0.005$). There were significant differences between FBP and 3D FLASH reconstruction in reducing the perfusion artifacts in right coronary artery (RCA) territories. Summed Rest Score (SRS) showed a significant decrease by 64 % ($p<0.01$) between the long-established FBP reconstruction and 3D Flash algorithm. **Conclusions**: 3D Flash-based reconstruction showed a significant improvement in image contrast and a decrease in many artifacts at the level of the inferior wall. **Keywords:** SPECT, MYOCARDIAL PERFUSION IMAGING, FBP RECONSTRUCTION, FLASH 3D.

Single-photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI) is widely used for direct assessment of myocardial perfusion (1, 2). Image reconstruction of the raw data is an essential step in the processing of cardiac SPECT images (3). The most commonly employed method that has been used for many years was filtered back-projection (FBP) algorithm. It is computationally fast, easy to implement and widely applied in clinical imaging. However, FBP reconstructed images are degraded by many factors, including distance-dependent blur, attenuation, scatter and noise which limits spatial resolution, degrade the image contrast and distort the shapes of the reconstructed objects (4).

Increased availability of computer resources and improvements in mathematical computation has led to the introduction of iterative reconstruction (IR) methods as alternatives for FBP in the heart. It is now widely accepted that IR algorithms can provide some advantages over the conventional FBP, by modeling the emission and detection process and compensate for scattering. Iterative reconstruction methods can produce images that are of higher spatial resolution, lower noise, higher contrast and improved detection of myocardial perfusion defects (5-7). Moreover, depth-dependent resolution recovery (RR) with SPECT has been developed, and its positive impact on the resolution has been reported (8).

The proposed Siemens Flash 3D is a SPECT tomographic reconstruction algorithm based on Ordered Subsets Expectation Maximization (OSEM) iterative method that incorporates a measured 3-D beam model for collimation in the iteration process (9, 10). Using proprietary algorithms, a new SPECT tomographic reconstruction algorithm was developed for use on Siemens gamma cameras. With Flash 3D all slices are reconstructed simultaneously and not successively in the interactive calculation. The full information content of the reconstruction volume is used by Flash 3D in the reconstruction, providing increased accuracy over earlier approaches that relied on less sophisticated resolution recovery methodologies of the projection data.

The goal of the current investigation was to evaluate the introduced Flash 3D reconstruction algorithm in MPI, and determine whether this image reconstruction protocol optimized for resolution recovery produced adequate imaging outcomes as compared with conventional FBP.

MATERIAL AND METHODS

Subjects. The study involved 36 patients - 10 (28%) males, 26 (72%) females, median age 61 years, range 41-80 years, with known or suspected diastolic heart failure and low risk for myocardial ischemia. All subjects underwent rest imaging according to *American Society of Nuclear Cardiology* (ASNC) imaging guidelines. The study was conducted according to the principles of the Declaration of Helsinki and was approved by the local ethics committee.

Hemodynamic data, including heart rate, systolic blood pressure, and diastolic blood pressure, were recorded at the beginning at the study.

SPECT Imaging Protocol. All patients underwent resting myocardial perfusion SPECT. Images were acquired at 45 minutes after intravenous administration of 15-20 mCi (555-740 MBq) of 99 mTc-Tetrofosmin. All studies were completed with a 90°-angled dual-head Symbia Evo Excel or Siemens e.cam gamma camera equipped with low-energy, high-resolution collimators. Patients were placed in the supine position with arms up, and automatic body contouring was used to obtain the optimum detector-to-patient distance. Emission data were acquired with a 20% energy window centered at 140 keV. Further acquisition parameters were 3° per step, 180° each head, and 25 s per projection.

Data analyses. All data were reconstructed with both FBP (Butterworth filter, order 5, cut-off 0.35) and 3D Flash (10 iterations, eight subsets, Gaussian filter, FWHM= 9.60) using the same workstation (fig.1).

Reconstructed image quality was characterized using three quantitative criteria: contrast (C), the contrast to noise ratio

(CNR) and signal to noise ratio (SNR). The image contrast was calculated between two regions of interest (ROIs) drawn inside the LV wall and cavity. The noise was estimated as the standard deviation of the mean number of counts of the myocardial ROI. CNR and SNR were determined as the ratio between contrast over the noise, respectively as the ratio between the mean number of counts over the noise (fig. 2).

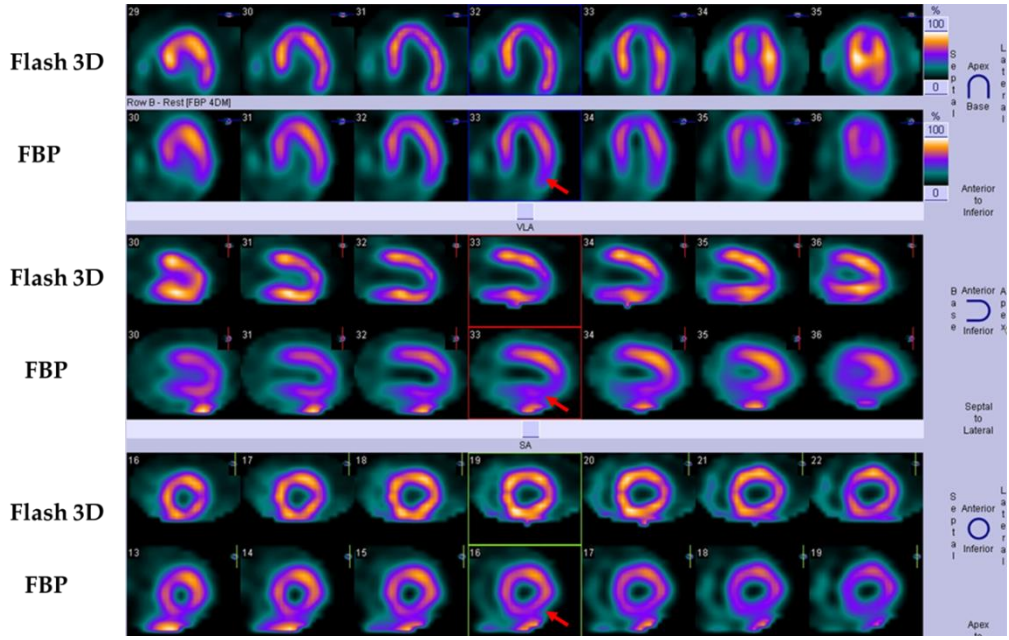

Fig. 1. Comparison of images reconstructed with FBP and 3D Flash. Note the presence of an inferior and lateral wall perfusion defect on FBP reconstructed images indicating inhomogeneous myocardial perfusion at the level of the inferior and lateral wall (arrow). Images reconstructed with Flash 3D shows no defect, suggesting that this was an artifact. Also, a better contrast between the left ventricular walls and cavity and better visualization of the right ventricle.

$$C = \frac{A_{Myo} - A_{Cavity}}{A_{Myo} + A_{Cavity}} \times 100$$

$$CNR = \frac{C}{\sigma Myo}$$

$$SNR = \frac{A_{Myo}}{\sigma_{Myo}}$$

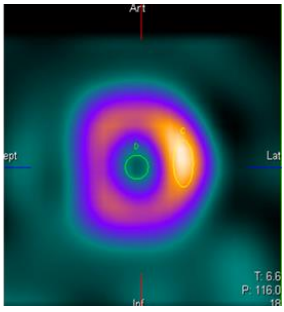

Fig. 2. Calculation of the image contrast (C), contrast to noise ratio (CNR) and signal to noise ratio (SNR) and the corresponding ROI´s.

Polar map displays of extent and severity were automatically generated for both methods and compared with a normal database using Quantitative Perfusion SPECT (QPS, Cedars-Sinai Medical Center, Los Angeles, CA, USA) software suite. The summed rest score (SRS) was used to measure cardiac perfusion inhomogeneity. For each coronary artery distribution, a perfusion score was automatically assigned, by comparing the polar maps of the patients with a database for normal persons under the same physiological conditions, gender, and isotope used (99mTc). A reconstructed image was interpreted without artifacts if the radiopharmaceutical distribution was homogeneous throughout the polar map display and the quantified perfusion score was 0 as compared with the database (fig. 3). A score of one, which represents an equivocal or mild reduction in perfusion, was considered an artifact introduced by the reconstruction algorithm.

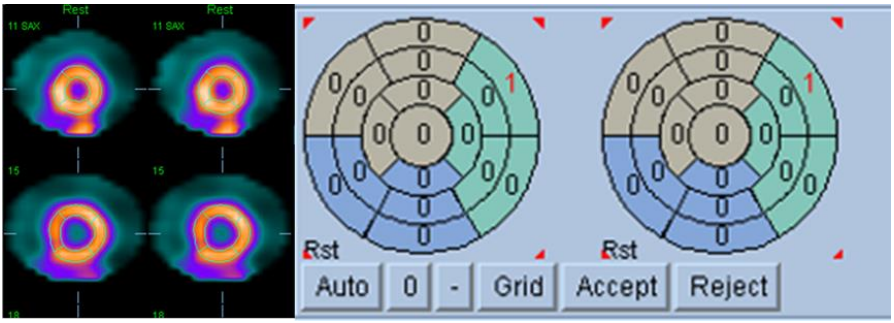

Fig. 3. Summed Rest Score (SRS) depicting mild reduction of tracer uptake in the territory of LCx artery.

Statistical analyses. Student's t-test for paired samples was employed to compare image quality parameters and the estimates of left ventricle perfusion abnormalities (summed rest scores) between the two reconstruction methods. Numeric results are expressed as mean ± SD. All statistical tests were performed with MedCalc for Windows (version 11.3.8.0 MedCalc Software, Mariakerke, Belgium). In all analyses, a p-value of less than 0.05 was considered statistically significant.

RESULTS

Image Quality Evaluation. 3D Flash reconstruction algorithm significantly increases image contrast by 31% ($p<0.005$). 3D Flash also demonstrated that, at identical dose levels, the contrast to noise ratio and signal to noise ratio are slightly decreased (tab. I).

TABLE I

Image quality evaluation parameters during stress and at rest.

Parameter	FBP	3D Flash
Contrast (%)	11	42*
Contrast to Noise Ratio	0.71 ± 1.49	0.63 ± 0.36
Signal to Noise Ratio (SNR)	9.34 ± 2.93	8.56 ± 3.23

*p < 0.005 vs. FBP; FBP - filtered back projection.

Perfusion abnormalities induced by reconstruction method. A total of 108 coronary artery territories were evaluated for perfusion abnormalities with both SPECT

reconstruction methods. The coronary artery territories to which the abnormal perfusion was found were as follows: on images reconstructed by FBP defects were found in 7 left anterior descending artery (LAD) territories in 16 left circumflex artery (LCx) territories and in 16 right coronary artery (RCA) territories, while on images reconstructed using 3D Flash in 2 LAD, 10 LCx and in 9 RCA territories. There were significant differences between FBP and 3D FLASH reconstruction in reducing the perfusion artifacts in RCA territories (16 vs. 9, $p= 0.008$) and no statistically significant differences in LAD territories (7 vs. 2, $p>0.05$) or LCx territories (16 vs. 10, $p>0.05$). Summed Rest Score (SRS) showed a significant decrease by 64 % ($p<0.01$) between the long-established FBP reconstruction and 3D Flash algorithm.

DISCUSSION

The present study was performed to assess the feasibility of the 3D Flash reconstruction algorithm which has been reported to improve noise properties by applying compensation techniques for photon attenuation, Compton scatter and depth-dependent resolution as compared to conventional reconstruction method using FBP (10, 11, 12). Our results indicate that there is an increase in image contrast between the myocardial wall and the left ventricular cavity by 31% for 3D Flash reconstructed images. Differences in perfusion scores were encountered in individual coronary artery territories with Flash 3D against FBP, except the RCA vascular territory where the mean difference in perfusion scores was significantly increased. Concerning individual vascular territories, the disagreements between the two types of reconstruction were mostly in the RCA and LCx arteries. This is probably due to the effect of sub diaphragmatic activity and diaphragmatic attenuation especially the case of the inferior wall. This finding may suggest that, although the compensation techniques for the photon attenuation and scatter might be effective with Flash 3D, it does not decrease the difficulties associated with the inferior wall attenuation artifacts (13). Nevertheless, the use of a standard template of coronary arteries distribution in MPI perfusion analysis may have also influenced. For instance, if a perfusion defect lies in the RCA territory, slightly increased perfusion defect size in Flash 3D reconstruction will incorporate part of the LCx territory as well (14). Summarizing, Flash 3D algorithm provides superior results as compared to conventional FBP by increasing the image contrast between the myocardial wall and the left ventricular cavity. With FBP reconstruction the CNR and SNR values were higher, with a trend toward decreased values in Flash 3D reconstructed images that are consistent with a slight increase in image noise. This could be related to the increased number of iterations and subsets used in our study (10 iterations, eight subsets) which may have an additive effect on noise as it has been suggested by other researchers (15). Anyhow, Flash 3D reconstructed images are improved quantitatively by increasing the absolute values of image contrasts, while CNR and SNR values remain approximately equal to those measured in the FBP reconstructed images.

CONCLUSIONS

Our study proved that Flash 3D algorithm was superior to conventional FBP reconstruction by increasing image contrast and diminishing inferior wall artifacts. Both FBP and iterative methods are useful, but the latter are now preferred since they offer more accurate modeling of physical processes.

PREVALENCE OF MATERNAL HYPOTHYROIDISM COMPLICATED WITH PREECLAMPSIA: A RETROSPECTIVE ANALYSIS OF 60 CASES (Abstract): **Aim:** We sought to determine whether there is an increased prevalence of hypothyroidism in pregnancies complicated with preeclampsia. **Material and methods:** We performed a retrospective analysis of 60 pregnancies complicated with preeclampsia and managed in our departments. FT3, FT4 and TSH levels were recorded, as well as the mode of delivery, and were compared to a control group of healthy normotensive women of similar demographic data. **Results:** Median gestational age was the same among study and control group. Cesarean section rate was higher in the study group, whereas median birth weight was higher in control group, but both differences did not reach statistical significance. More low birth weight infants were delivered by hypothyroid mothers and this was marginally significant. In preeclamptic women mean TSH value is significantly increased when is compared to mean TSH at healthy normotensive women of similar demographic data. Free triiodothyronine (FT3) and free thyroxine (FT4) levels were similar among preeclamptic and normotensive pregnant women. **Conclusions:** Subclinical hypothyroidism is more common in preeclamptic than in normotensive pregnant women. **Keywords**: MATERNAL HYPOTHYROIDISM, PREECLAMPSIA, PREVALENCE, PREGNANCY.

It is well documented that during pregnancy occur substantial, but reversible physiologic changes in thyroid function and some authors implicate for that the elevated levels of circulating estrogens (1, 2). While preeclampsia occurs in about 8% of all pregnancies, it is observed in 16.7% of pregnancies complicated by subclinical hypothyroidism and in 43.7% of pregnancies with overt hypothyroidism (3). There are a few reports that have studied thyroid hormone status in preeclamptic women showing that hypothyroidism is more common than in normotensive women, and indicating that increased incidence of hypothyroidism might correlates with the severity of preeclampsia (4, 5).

The physiologic mechanism that would explain the higher incidence of hypothyroidism in preeclamptic women is not yet delineated, but low concentrations of thyroid hormones are attributed to decreased

plasma protein concentrations and elevated levels of endothelin, a vasoconstrictor produced by vascular endothelium (6). In the latter case, vascular endothelial damage, which raises levels of endothelin, is implicated in the pathogenesis of subclinical hypothyroidism in preeclampsia. To shed light on this aspect, we evaluated thyroid hormone levels in pregnant women with preeclampsia in the third trimester and correlated it with obstetric outcome.

MATERIAL AND METHODS

In the present study, we evaluated thyroid hormonal status of 60 pregnant women who were admitted in the 3rd Department of Obstetrics and Gynecology of the University of Athens and Rea Hospital of Athens during the last six years with a diagnosis of preeclampsia at the third trimester of their pregnancy.

Free triiodothyronine (FT3), free thyroxine (FT4) and thyroid stimulating hormone (TSH) were evaluated at the time of diagnosis of preeclampsia. TSH was measured by immunoradiometric assay and the normal nonpregnant level in our hospital is 0.1-5.5 mIU/L. Also, we recorded the mode of delivery, gestational age at delivery and birth weight.

Control group consisted of equal number of healthy normotensive pregnant women, with similar demographic data (age, race, residence, weeks of gestation). In both groups - study and control - women with other pathological conditions were excluded. Women with other conditions associated with adverse obstetric and neonatal outcomes, such as diabetes, multiple gestation, other endocrine diseases, infections, rheumatologic diseases, were also excluded.

Preeclampsia was diagnosed on those cases where blood pressure was at least 140/90 mmHg in two consecutive measurements, after the 20th week of gestation. In all the preeclamptic cases proteinuria was diagnosed with urine test at the moment of admission.

Results are expressed as median values with their range interval where necessary. Comparisons between two groups by the Wilcoxon signed rank test and Mann-Whitney test where appropriate. Statistical analysis of demographic data and hormone levels between groups were performed with the *t-Student* test and X^2 test (for delivery route).

RESULTS

In the present study 60 pregnant women were investigated concerning their thyroid hormonal status and the possible relationship between hypothyroidism and preeclampsia.

Mean gestational age at the time of admission and diagnosis was 35.2 ±2.6 weeks in the study group and 36.1±2.5 weeks in the control group. Median age of the preeclamptic women was 29.2±5.6 years and 28.8±4.2 years at the control group. There was no statistically significant difference between age and week of gestation between the two groups.

On the contrary, there were statistically significant differences regarding gestational age at delivery and birth weight among control and study group. Preeclamptic women delivered earlier (37.1±1.2 weeks) than the control group (38.6±1.1 weeks) ($p<0.001$).

Furthermore, mean birth weight in the control group was 3.2±0.3 kg, whereas in study group was 2.85±0.35 kg ($p<0.05$). The mode of delivery (vaginal *vs* cesarean section) occurred to be without significant statistical difference: 50 women (83.3%) of the study group delivered with cesarean section, compared to 46 (76.6%) of the study group (tab. I).

TABLE I.

Clinical and demographic characteristics

Characteristics	Control group	Study group	p-value
Maternal age (years)	28.8±4.2	29.2±5.6	NS
Gestational age at admission (weeks)	36.1±2.5	35.2±2.6	NS
Gestational age at delivery (weeks)	38.6±1.1	37.1±1.2	<0.001
Delivery mode			
Vaginal	14	10	NS
Cesarean	46	50	NS
Birth weight (kg)	3.2±0.3	2.85±0.35	<0.05

Concerning the thyroid hormone status, mean FT3 and mean FT4 levels were not significantly different (NS). TSH mean levels were significantly higher in the preeclamptic group ($p<0.001$) (tab. II).

TABLE II.

FT3, FT4, TSH levels in the study and in the control group (*p<0.001: Mann-Whitney test)

Thyroid hormone status	Normal range	Study group		Control group	
		Mean	SD	Mean	SD
FT3 (pg/mL)	1.7-5.2	3.45	2.2	2.8	1.50
FT4 (ng/mL)	0.6-2.4	0.7	0.42	0.7	0.42
TSH*(mIU/L)	0.5-5.1	4.4	3.6	2.4	2.15

In the control group only 5 women (8.34%) had TSH levels higher than 5.1 mIU/L, whereas the study group had 28 cases (46.67%) (tab. III).

TABLE III.

Distribution of normal and abnormal TSH levels

	TSH <5.1 (mIU/L)	TSH >5.1 (mIU/L)
Control group	55 (91.66%)	5 (8.34%)
Study group	32 (53.33%)	28 (46.67%)

DISCUSSION

There are a few reports addressing the question whether hypothyroidism and preeclampsia are associated, or if hypothyroidism when appearing in preeclampsia is a marker of adverse obstetric outcome.

Davis et al (7) showed that among 16 women with overt hypothyroidism, 7 were preeclamptic and 5 had a history of chronic hypertension. Morbidity and mortality in this population was substantially higher and was associated mostly to *abruptio placentae* and preeclampsia.

It is known that hypothyroidism can lead to vascular smooth muscle contraction in systemic and renal vessels, resulting in

increased peripheral vascular resistance, diastolic hypertension, and decreased tissue perfusion. Interestingly there are a few case reports suggesting that hypothyroidism can also cause proteinuria, indicating that maybe hypothyroidism is the cause for preeclampsia and not the other way around. Ogata et al (8) reported a case of a 65-year-old woman with proteinuria, edema, weight gain, and renal dysfunction due to discontinuation of T4 therapy, with renal biopsy revealing focal segmental proliferative glomerulonephritis. Restoration of thyroid hormone levels lead to recovery of renal function. Lastly, Alfadda & Tamilia (9) describe a case of overt hypothyroidism in a 20-week pregnant woman that was associated with a preeclampsia-like syndrome and fetal death.

In the present study, we found that mean TSH is significantly increased in preeclamptic patients when compared to control group. We didn't registered differences among the study and control group regarding FT3 and FT4. These results are in accordance to other reports where subclinical hypothyroidism is more common in preeclamptic than normotensive pregnant women (2, 4, 5).

We should point out that Leung et al (10) report that women with overt or subclinical hypothyroidism before pregnancy had a higher incidence of gestational hypertension, implying that incidence of low birth weight infants in women with overt hypothyroidism is due to increased incidence of preterm delivery, which is related to gestational hypertension. In this study, maternal hypothyroidism did not correlate with adverse obstetric and neonatal outcomes.

Mild changes in thyroid hormonal status may occur due to various stress factors, irrespectively to thyroid diseases, as well as to decreased plasma albumin concentrations (11). Also, there are suggestions that the decrease of thyroid hormones is caused by the loss of protein and protein-bound hormones in the urine (12).

Lao et al (4) found that preeclamptic women with lower thyroid hormones and increased TSH levels were more likely to deliver small for gestational age (SGA) infants than euthyroid women. These results were confirmed by Kaya et al (5) that showed that serum total T4 and total T3 concentrations in women with SGA infants were significantly lower than in women with AGA infants. These two investigators though did not agree on the possible correlation between birth weight and TSH levels. Whereas Lao et al (4) also reported a negative correlation Kaya et al (5) found that total T4 and T3 levels in preeclamptic and eclamptic women correlated positively with birth weights. Basbug et al (14) in agreement to Kaya et al (5) results revealed significant correlations between birth weights, total T4 and T3 levels in preeclamptic and eclamptic women.

Lao et al (4) showed that total T4, total T3, and free T3 correlated significantly with plasma albumin and urate concentration, indicating that thyroid hormonal status could reflect severity of preeclampsia, since decreased plasma albumin concentrations, correlate with low birth weights in preeclampsia. This conclusion is also supported by Basbug et al (13), that showed that maternal endothelin levels correlated with all thyroid function tests.

There are indications that low birth weight infants might have a mechanism to prevent decreases in free T4 concentrations associated with total T4 concentrations (14) and this hypothesis explains why a signifi-

cant correlation between birth weight, total T4, and total T3 exists, but not between birth weight, free T4, and free T3 among infants of preeclamptic and eclamptic subjects.

CONCLUSIONS

In preeclamptic women mean TSH value is significantly increased compared to mean TSH at healthy normotensive pregnant women of similar demographic data.

Free triiodothyronine (FT3) and free thyroxine (FT4) levels were similar among preeclamptic and normotensive pregnant women.

Maternal hypothyroidism did not correlate with adverse obstetric and neonatal outcomes.

Our study results support the statement that subclinical hypothyroidism is more common in preeclamptic than in normotensive pregnant women.

CLINICAL, LABORATORY AND THERAPEUTIC PROFILE OF LICHEN PLANUS (Abstract): **Aim:** Retrospective study of the clinical manifestations and clinical forms of lichen planus, investigation methods and therapeutic means using data from patients admitted to the Dermatology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital Iasi, in the interval January 1st-December 30th, 2015; the obtained results were compared with the data in the literature. **Material and methods:** Forty-five patients were included in the study. The data were interpreted by using various statistical notions: arithmetic mean, percentage distribution, standard deviation, coefficient of variation, "t-Student" test. Histopathological examination was performed in most cases to enhance diagnosis certainty. **Results and discussion:** The analysis of the study group (29 women and 16 men) produced many results in agreement with literature data. In 2015 the prevalence of lichen planus in the patients admitted to the Clinic of Dermatology, regardless of clinical form was 4.01% with a female preponderance (female/male ratio 2: 1). The mean age of the study patients was 55.31 years and 79.98% of total cases were in the fourth and six decades of life. The main infectious risk factor for the development and progression of lichen planus is hepatitis C virus (13.3%). The most common form of lichen planus (88.8%) was the cutaneous form. **Conclusions:** Lichen planus is a chronic autoimmune disease with undulating course and different clinical subtypes that can affect multiple body regions**. Keywords**: LICHEN PLANUS, PAPULE, AUTOIMMUNE DISEASES, LICHENOID REACTIONS.

Lichen planus is a mucocutaneous inflammatory dermatosis of uncertain etiology, with chronic or subacute course, often self-limited (1). The classic description of lichen planus eruption is given by the 5 Ps: purple, planar, polygonal, pruritic, papules (2).

The estimated prevalence of lichen planus in the general population is in the range of 0.2% to 4%. It occurs more fre-

quently in the fifth or sixth decades of life, predominantly in women. Lichen planus in children is uncommon, but cases with familial aggregation have been reported (3).

The cause of lichen planus is still unknown. The etiologic hypotheses include genetic, infectious, psychological and autoimmune factors (1).

Lichenoid eruptions (LDE-probably a type IV hypersensitivity reaction) are reactive mucocutaneous lesions that are nearly identical clinically and histologically with those in idiopathic lichen planus. Drugs more frequently associated with LDE are the synthetic antimalarials, gold salts, D-penicillamine, methyldopa, B-blockers, angiotensin-converting enzyme inhibitors, spironolactone, nonsteroidal anti-inflammatory drugs, thiazide, phenothiazine derivatives, allopurinol, tetracycline, sulphonylurea (1).

Notable is the association of lichen planus with such autoimmune diseases as systemic lupus erythematosus, myasthenia gravis, dermatomyositis, ulcerative colitis, chronic active hepatitis, pemphigus vulgaris, dermatitis herpetiformis, bullous pemphigoid, alopecia areata, vitiligo, Sjogren's disease, systemic sclerosis. It supports the immunological hypothesis in the pathogenesis of lichen planus (1).

MATERIAL AND METHODS

This open and retrospective study was conducted on a sample of 45 patients admitted with a diagnosis of lichen planus to the Dermatology Clinic of the "Sf. Spiridon" Clinical Emergency Hospital Iasi between January 1st and December 30th, 2015.

Data on clinical manifestations, clinical forms, investigation methods and therapeutic approaches were collected. The obtained data allowed us to classify the patients by gender, age, area of residence, etiology, affected areas, clinical form of lichen planus, association with certain diseases, type of administered treatment and its efficacy, and to compare the obtained results with the literature data. The clinical and histopathological examinations proved to be essential in making the diagnosis. In patients who experienced multiple hospitalizations we focused on the criteria for evaluating treatment efficacy and occurrence of side effects.

For data interpretation, we used various statistic notions: arithmetic mean, percentage distribution, standard deviation (to highlight dispersion of data around the calculated value), coefficient of variation (which is an index of dispersion used to compare statistical series), student's t test (indicating the presence or absence of a significant difference between the two means and between two statistical series that could be correlated with the intervention of objective factors).

RESULTS AND DISCUSSION

In 2015 the prevalence of lichen planus in the patients admitted to the Clinic of Dermatology, regardless of clinical form was 4.01%. Per the literature data, the estimated prevalence of lichen planus in the general population is in the range of 0.2% to 4% (3), with geographic area variations.

Among the study patients the urban/rural ratio was 1:1.5. This difference could be related to prolonged occupational sun exposure (farming), multiple studies suggesting a relationship between exposure to ultraviolet (UV) light and disease severity, while improvement in lesions is obtained using UV protection (4).

There was a female preponderance in our study (female/male ratio 2: 1) (fig. 1), result in accordance with the literature data (5).

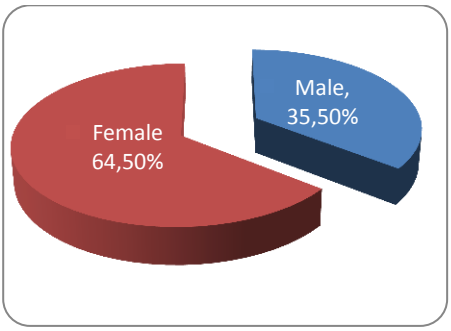

Fig. 1. Sex distribution of the lichen planus patients

The mean age of the study patients was 55.31 years (range 9 to 87 years). The data are consistent with the literature data, per which lichen planus may occur at any age, with a peak incidence in the third to the sixth decades of life (5). In this study, 79.98% of total cases were in the fourth and six decades of life (fig. 2). A case of childhood lichen planus was recorded in a 9-year-old girl, accounting for 2.22% of all cases, but without familial aggregation of lichen planus (6).

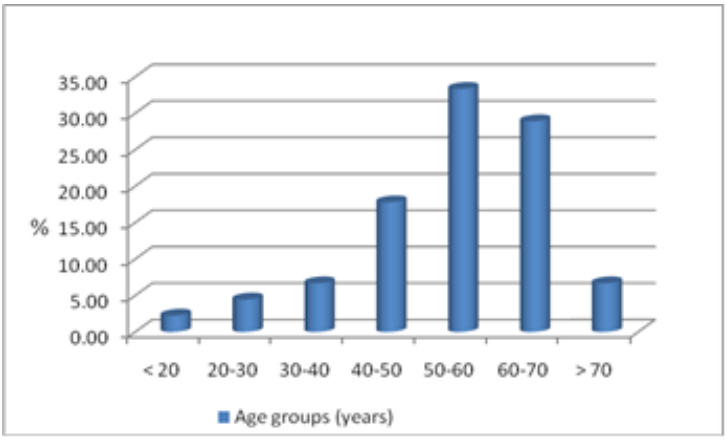

Fig. 2. Percentage distribution by age-group of lichen planus patients

As for the clinical manifestations of lichen planus, the study protocol aimed to analyze the following: disease history, general and local physical examination, association with other diseases. The onset was insidious in most cases, with a progressive development of symptoms and lesions.

Of the medications administered prior to the occurrence of the disease the most common were the drugs for cardiovascular diseases (66.66%) and non-steroidal anti-inflammatory drugs (15.6%), drug classes known as having an important role in the onset or further progression of lichen planus.

Another factor responsible for the development and progression of lichen planus is the infectious one, hepatitis C virus being the most studied agent. Laboratory investigations revealed that 6 (13.3%) of the study patients had chronic hepatitis C, a high percentage considering that the seroprevalence of hepatitis C virus in the general population is about 5% (7). These patients presented mucocutaneous involvement. Other viral infections incriminated are those with herpes family of viruses: herpes simplex, Epstein-Barr, cytomegalovirus and herpesvirus 6. *Helicobacter pylori* infection (8) was detected in 3 patients.

Local physical examination is useful for the classification of lichen planus cases based on clinical form, lesion morphology and anatomical region.

Of the 45 patients, 40 (88.8%) had cutaneous LP, 5 presented only mucosal involvement (11.1%), and 15 patients both cutaneous and mucosal involvement, accounting for 33.3% of all cases (per the literature data, 30-70% have lichen planus with mucosal involvement (5)).

In the 40 cases of lichen planus with cutaneous involvement, the most common morphological subtype was represented by the classic form (18 cases, 45%) (fig. 3).

Fig. 3. Flat, polygonal, erythematous-violet, small, shiny, isolated, itchy papules on the flexor surface of the hand (classic lichen planus)

The second most common subtype was the atrophic form. Long-term use of potent and super potent topical corticosteroids may lead to the development of this form of lichen planus. In the present study, only 2 of the 7 patients with atrophic lichen planus were known to have lichen planus and were on treatment, the remaining 5 being at their first hospital admission.

Other common subtypes were the hypertrophic subtype, 5 patients (fig. 4), and follicular subtype, 5 patients (fig. 5), 4 of them women presenting alopecia plaques on the scalp and one male patient with lesions on the chest.

Fig. 4. Multiple papular, itchy, violaceous lesions, arranged in a reticulate fashion (hypertrophic lichen planus)

Fig. 5. Flat, follicular, polygonal, erythematous-violet, bright, isolated papules on the scalp (follicular lichen planus)

Of the 45 patients included in this study 20 (44.4%) presented mucosal involvement. Oral lesions were the most common, and most patients were females (tab. I).

Of the 13 patients with oral involvement 7 presented the reticular form, which is the most common form. Five patients had the erosive form, the symptoms consisting of pain, burning sensation, sometimes dysphagia. One of these 7 patients,

an 87-year-old male, presented atrophic-erosive lichen planus lesions (fig. 6).

TABLE I
Distribution of mucosal lesions by anatomical areas

Affected mucosal region	Number of patients		Total	%
	Males	Females		
Oral cavity	4	9	13	60
Genital mucosa	3	7	10	40
Total	7	16	23*	100

*the total corresponds to 23 patients as some of them presented both oral and genital involvement

Fig.6. Exulceration, slightly depressed, irregular contour, painful, covered by a pseudo membrane

Seven patients (24.13%) presented vulvovaginal involvement, of which 5 (17.24%) with the erosive form, sometimes in association with atrophic lesions. Three (10.34%) of these presented complications, the most common being represented by the agglutination and resorption of the labia minora, accompanied in 2 cases (6.89%) by the narrowing the vaginal ostium. Included in this group was a case (3.44%) of vulvo-vaginal-gingival syndrome, the patient associating erosive vulvovaginal and oral lichen planus at the level of jugal mucosa.

Genital involvement was found in 3 males (18.75%), 2 with the erosive form and one with the classic papular form.

In this study, the diseases most frequently associated with lichen planus were hypertension, diabetes mellitus and chronic venous insufficiency.

A number of autoimmune diseases have been found to be associated with lichen planus: alopecia areata (2 cases, 4.44%), autoimmune thyroiditis/Graves' disease (6 cases, 13.3%), systemic lupus erythematosus (3 cases, 6.66%), vitiligo (3 cases, 6.66%), vasculitis (1 case, 2.22%), plaque morphea (1 case, 2.22%), scleroderma (1 case, 2.22%), pemphigus vulgaris (2 cases, 4.44%), psoriasis (2 cases, 4.44%), making a total of 21 patients, representing 46.6% of the study group. Also, the association with hypersensitivity reactions is mentioned in numerous studies (9): arthritis (3 cases, 6.66%), allergies to various compounds (8 cases, 17.7%), asthma (1 case, 2.22%), gastritis (2 cases, 4.44%), atopic dermatitis (1 case, 2.22%), making a total of 15 patients (33.33%). The results are consistent with the data in the literature and support the autoimmune theory (1).

The triad of oral lichen planus, diabetes mellitus and hypertension, association known as Grünspan's syndrome was found in two patients (4.44% share).

The results of laboratory investigations are nonspecific, excluding direct and indirect immunofluorescence, immunohistochemistry and histopathology.

Histopathological examination was performed in most cases to enhance diagnostic certainty, in agreement with the data in the literature (10). The most common changes are the orthokeratotic hyperkeratosis, hypergranulosis, acanthosis, tapered rete ridges, band-like lymphoplasmocytic inflammatory infiltrate at the dermo-epidermal junction the presence of Civatte bodies (apoptotic keratinocytes). These are exemplified in the following iconography,

with images of biopsies collected from our patients (fig. 7, 8, 9, 10).

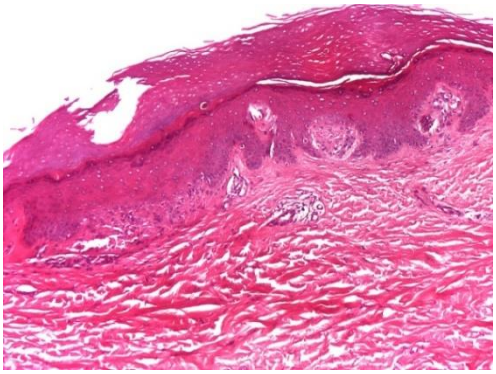

Fig. 7. Hyperkeratosis, hypergranulosis, acanthosis – Classic lichen planis. HE 4x

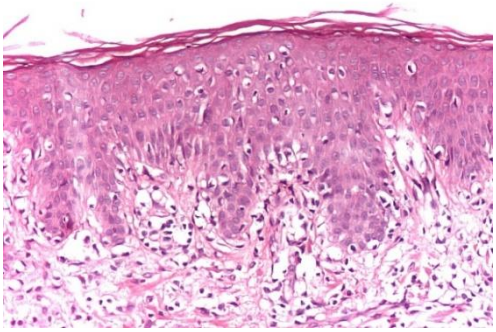

Fig. 8. Spongiosis with exocytosis, Civatte bodies – Lichenoid eruption. HE 10x

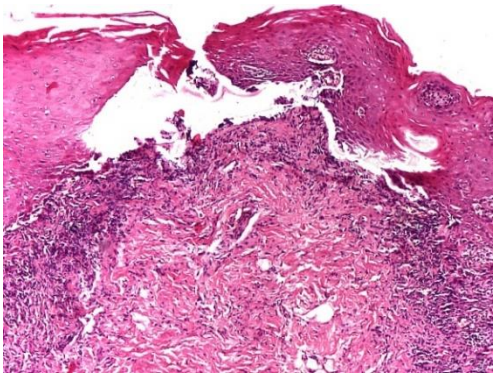

Fig. 9. Submucosal bullae – Oral lichen planus. HE 4x

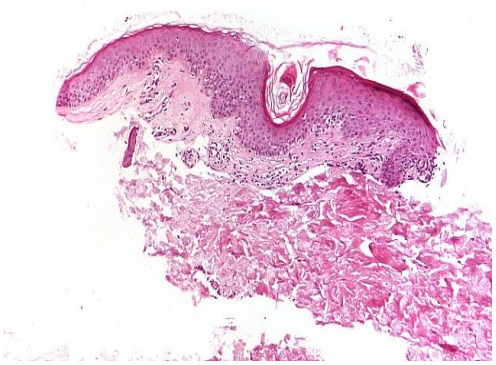

Fig. 10. Discrete perifollicular inflammatory infiltrate – Follicular lichen planus. HE 4x

Regarding the treatment of lichen planus, the following ones were mainly administered: topical (88.88%), systemic (17.7%) and intralesional corticosteroid therapy (2.2%), therapy with immunosuppressive agents (2.2%), PUVA therapy (2.2%), antihistamines (93.3%), vitamin C (88.8%) and calcium gluconate (82.2%) (as adjuvants to the main therapy). The main treatment option was topical corticosteroids and in 6 cases (13.3%) was also associated systemic therapy. Systemic corticosteroid therapy was used in 8 cases (17.7%) of lichen planus with severe multiple of both the skin and mucous membranes. Thus, 4 of these cases (8.8%) had rash extended and oral lesions insufficiently responsive to topical treatment, and 3 cases (6.6%) with rash, erosive oral and genital, only one case of lichen planus eruptive generalized unresponsive to topical therapy. Individualized treatment regimens were tailored for each patient, their efficacy, occurrence of possible side-effects and the interaction with the medication used to treat the associated diseases associated being closely monitored.

The course and prognosis are generally favorable, most patients (73.3%) showing

complete or partial remission of the lesions on treatment. In the patients (26.6%) with persistent lesions the treatment was reconsidered. Clinical forms with negative evolution or absence of remission were the mucosal lichen planus cases, both the oral and genital mucosa. 6 patients (13.3%) had various complications. Thus, three of them (6.6%) suffered diffuse or localized cicatricial alopecia, one man (2.2%) with erosive lichen planus genital complicates with phimosis, and two females (4.4%) develop agglutination of labia minora. Given the risk of complications, sometimes debilitating in lichen planopilaris and mucosal lichen planus, and of malignant transformation of the erosive mucosal forms, patients were informed about these risks and periodic clinical, biological and therapy reassessment visits were recommended.

CONCLUSIONS

The profile of the patients enrolled in this study is consistent with the data in the literature. Thus, our findings emphasize frequently with the association between liver damage and lichen planus, especially HCV infection (6 patients, 13.3%) and cirrhosis (3 cases, 6.6%). In our study, dyslipidemia was found in 48.88% of cases with lichen planus, the most frequent association was made with the cutaneous form (35.5%) followed by the oral (22.2%) and genital form (8.88%). In 2016, Lai YC et al (12) published similar results regarding the association between lichen planus and dyslipidemia. Although, palm-plantar lichen is very rare (1-2% according the literature), in our study it was present in 10% of cases, being characterized by multiple, bilateral lesions associated with severe pruritus. Forward studies will explain this statistics results.

Lichen planus may have a psychosocial impact affecting the quality of life of patients, our study revealing that 8.8% of cases were diagnosed with depression. Giving attention to pathogenesis, clinical picture and an early diagnosis are essential for selecting the most appropriate treatment. Our data referring to the therapeutic options have been aligned with European standards of treatment. Given the undulating nature of the disease, periodic monitoring of disease course and therapeutic efficacy are required.

NEWS

CDH17 IS A MORE SENSITIVE MARKER FOR GASTRIC ADENOCARCINOMA THAN CK20 AND CDX2

Metastatic cancers can be difficult to diagnose in a clinical setting with most being carcinomas. In the past, a panel consisting of cytokeratin (CK) 7, CK20, and CDX2 antibodies has been used to assess gastrointestinal (GI) tumors of unknown primary. Expression of CK7 is observed in a wide variety of carcinomas, thus, it is an important marker in diagnosis. CK20 expression is specific to certain types of cancer and is typically used in combination with CK7 to distinguish different types of tumors. CDX2 is a homeobox gene that encodes an intestine-specific transcription factor and is expressed in the nuclei of epithelial cells throughout the GI tract. Immunohistochemical expression of CDX2 protein in primary and metastatic colorectal carcinomas has been previously documented. CK7 along with CK20 or CDX2 markers constitute an important panel for the diagnosis of GI tumors versus tumors of unknown origin. However, in difficult cases, expression patterns may vary and the presence or absence of these markers may not lead to a definitive diagnosis. Cadherin 17 (CDH17), also called liver-intestine cadherin, is a cell-adhesion protein that is transcriptionally regulated by CDX2, and is involved in tumor invasion and metastasis. CDH17 is a novel diagnostic marker for GI tract carcinoma with greater sensitivity than CDX2 in colon cancers. Recently, a mouse monoclonal CDH17 (clone IH3) antibody has been developed to aid pathologists in interpreting GI adenocarcinomas, especially in cases of unknown primary origin. There have been conflicting results with CDH17 antibodies, even when using the same designated clone as presented in this study. This study will present an immunohistochemical evaluation in a side by-side comparison with antibodies CDH17, CK20, and CDX2 in various neoplastic tissues, with emphasis on GI adenocarcinomas. CDH17 may also be helpful in cases that are negative for CK7, CDX2, and CK20. The study results confirm that CDH17 expression analysis may be of significant value in the diagnosis of GI tumors and those of unknown origin (Altree-Tacha D, Tyrrell J, Haas T. CDH17 Is a More Sensitive Marker for Gastric Adenocarcinoma Than CK20 and CDX2. *Arch Pathol Lab Med* 2017; 141: 144-150).

ATHEROSCLEROSIS IN THE YOUNG ADULT: FEWER HYPOTHESES, MORE FACTS

Corina Dima-Cozma*

*Corresponding author. E-mail: cdimacozma@yahoo.com

ATHEROSCLEROSIS IN THE YOUNG ADULT: FEWER HYPOTHESES, MORE FACTS (Abstract): Several studies have reported early atherosclerotic changes in arterial wall of young adults, although they usually become symptomatic after age 40 years. Initially, some sporadic and limited data were available to document the atherosclerotic lesions in young adults; early subclinical assessment were later possible using accurate ultrasound and other imaging techniques. Our aim was to a review of eloquent studies proving different type of atherosclerotic lesion in the young adult. Long-term follow-up and further analysis of this population demonstrated important relationship with traditional and some non-traditional, risk factors. The data comprised in the reviewed studies are arguments in favor of a more refined atherosclerotic risk assessment and appropriate preventive strategy in young adult.
Keywords: ATHEROSCLEROSIS, YOUNG ADULT, CARDIOVASCULAR RISK, NON-INVASIVE CARDIOVASCULAR TESTING.

Atherosclerosis is an active systemic pathobiological process, usually clinically expressed and complicated in adulthood and elderly (1). However, previous autopsy studies (2), or, more recently clinical investigations based on the latest subclinical methods (vascular and intravascular ultrasound, coronarography, computed tomography and magnetic resonance) showed subclinical or complicated atherosclerotic lesions in young adults, or even in teenagers or children (1-3). In Bogalusa Heart Study (2), an interesting approach was developed, combining autopsy information about the extent of vascular damage, with patient's history providing data about the presence of cardiovascular risk factors, collected prior to death. Significantly and persistently elevated blood pressure levels, adipose mass and dyslipidemia in young adults are markers of risk for progressive coronary atherosclerosis. Abdominal and visceral obesity, most commonly encountered and associated with metabolic syndrome, were strongly correlated, especially in males, with coronary atherosclerosis and, less well with aortic involvement (4, 5).

Most cardiovascular risk factors assessed in clinical studies are correlated with the initiation and progression of the atherosclerotic disease. Atherosclerotic transformation of the arterial wall is the faster the more factors such as dyslipidemia, inflammation and thrombosis are precociously activated. Smoking, sedentary lifestyle and obesity are factors increasingly

encountered in teenagers and their overtime persistence will lead to early complications of atherosclerosis. Myocardial infarction is a frequent complication of coronary atherosclerosis in young adults, frequently represented by an isolated single lesion, still complicated by ulceration and thrombosis due to the persistence of a conglomeration of cardiovascular risk factors (2, 6).

Atherosclerosis in young adults was initially studied by sporadic autopsy information and later clinical studies. One of the main limitations of the systematic interpretation of the data in the clinical studies remains the arbitrary delimitation of the age intervals defining young adult. Some of the published articles have used mixed cohorts of patients, aged under or up to 18 years, or occasionally set an upper age limit for the young adult of 35 years and even 45 years. The first anatomical observation and invasive studies reported mainly the complications of atherosclerosis such as stroke or myocardial infarction, while the modern approach is non-invasive and allows imaging assessment of subclinical atherosclerosis in several categories of young adults (1, 2, 4-6). This review outlines the most significant data published on adults aged 18 to 45 years, with emphasis on subclinical atherosclerosis beside the presence and extent of complications.

EPIDEMIOLOGICAL APPROACH

The epidemiological data were collected from morphological and clinical surveillance studies. Some of the earliest findings were obtained from autopsy specimens collected from young soldiers killed in war battles (7, 8). At a mean age of 22 years, 70% of them already had coronary atherosclerotic lesions (8). Post-mortem coronary angiography showed minor changes in 45% and raised lesions in 5% of 105 soldiers killed in Vietnam war (7, 8). Bogalusa Heart Study provided significant data, describing the postmortem arterial morphological findings in subjects enrolled before their death and followed-up for a period for the description of the specific cardiovascular risk factors. The study enrolled 204 patients aged 2 to 39 years. Early atherosclerotic lesions, represented by fatty streaks, were reported in 50% of subjects aged 2 to 15 years and in 85% of subjects aged 21 to 39 years (8). Advanced atherosclerotic lesions, represented by raised fibrous - plaque, were mentioned in 8% of subjects aged 2 to 15 years and in 69% of subjects aged 26 to 39 years (2, 6, 8). PDAY Study (Pathobiological Determinants of Atherosclerosis in Youth) reported autopsy findings from 2876 subjects aged 15 to 34 years. Advanced atherosclerotic lesions were described in the abdominal aorta in 20% of patients aged 15 to 34 years and 40% of subjects aged 30 to 34 years. Right coronary artery showed pathological changes in 10% of subjects aged 15 to 19 years and in 30% of those 30 to 34 years (8, 9).

Autopsy studies have inherent limitations (artifacts caused during the processing of morphological samples or inconsistencies in the absence of *in vivo* hemodynamic conditions). Therefore, this kind of studies were followed by clinical evidence obtained with invasive or non-invasive methods. Tuzcu EM et al. (1) reported results obtained by coronary intravascular ultrasound performed within about 1 month after transplantation in 262 heart transplant recipients, the organ donors being young asymptomatic subjects (146 men and 116 women, mean age 33.4±13.2 years). Atherosclerotic lesions were present

in 136 patients (51.9%). Atherosclerosis prevalence is increasing significantly with age (17% in subjects aged under 20 years and 85% in subjects older than 50 years), without gender differences (52% in men and 51,7% in women) (1). In other studies, subclinical atherosclerosis was noninvasively assessed and it proved to be more frequent in young subjects with metabolic syndrome (5, 10), obesity and other cardiovascular risk factors (10-12). CARDIA Study demonstrated an increased incidence of coronary affectation in young adults with abdominal obesity (12).

ASSESSMENT OF SUBCLINICAL ATHEROSCLEROSIS

Over 20 years of research were needed to establish new methods and cardiovascular biomarkers that could be properly representative for the presence of subclinical atherosclerosis. The new methods have high applicability and maximum benefit if they prove fidelity in detection of atherosclerotic lesions, reproducibility and cost-efficiency, are non-invasive and standardized. Some of these methods have been developed more and are used to screen large populations and guide medical intervention to reduce the cardiovascular risk (13).

After 1990, accurate measurements of carotid intima - media thickness (cIMT) were possible using high - resolution B-mode ultrasonography. This imaging technique is non-invasive and accessible in large communities of all ages, gender and origin. Most of the studies demonstrated that cIMT could be correlated with aortic and coronary atherosclerosis, reflecting, at the same time, the adaptation of the arterial system to increased intravascular stress (13, 14). Accurate measurements require a standardized technique, approaching the common carotid, internal carotid and carotid bifurcation at several arterial sites. Currently, ultrasound apparatus should be equipped with a transducer greater than 8 MHz. A cIMT greater than 1 mm is considered abnormal. In term of prediction, it is important that single or average values measured for cIMT have the same power in correlation with future coronary events (13-15). Carotidian atherosclerosis is an independent predictor of stroke and myocardial infarction (16, 17).

Ankle-brachial index (ABI) has started as a simple and inexpensive test for diagnosis of peripheral arterial disease (PAD). In this regard, the most used was the protocol for the determination of ABI with the Doppler method. Usually, per the American Heart Association (AHA) protocol for the determination of the ABI with Doppler method, the calculation is made for each leg with the higher of the 2 ankle pressures (determined in tibialis posterior and dorsalis pedis arteries) in relation to the highest brachial systolic blood pressure (SBP) (18).

The sensitivity is ~ 90% and specificity ~ 98% in the presence of stenosis $\geq$ 50% in leg arteries. An ABI < 0.9 is considered abnormal. In terms of risk, the studies have reported a high incidence of cardiovascular morbidity and mortality in patients with pathological ABI values (19-21). The relevance of risk prediction is still debatable in persons $\geq$ 50 years old, where pathological values for ABI were more frequently found. Therefore, the importance of ABI as a predictor of atherosclerosis is more valuable in persons < 50 years old (17). Some authors have proposed a shift in the calculation of ABI, for the PAD diagnosis, and, particularly, when it is used as a general indicator of atherosclerosis and cardiovascular risk. For example, using the lower ankle

pressure instead of the higher ankle pressure between tibialis posterior and dorsalis pedis for each leg, ABI was associated with higher sensitivity, but with lower specificity in the diagnosis of PAD (22). In 831 patients who underwent coronarography, ABI was calculated using both formulas and the comparison showed that with the modified version more patients at high cardiovascular risk were identified (23).

The detection of coronary calcium by electron beam-computed tomography (EBCT) and helical computed tomography (CT) led to the identification of asymptomatic but high-risk coronary artery disease patient (17). Coronary artery calcification (CAC) score was correlated with pathological findings of atherosclerosis in coronary arteries (17, 24). Current guidelines discuss the indications for coronary CT, namely asymptomatic patients at high cardiovascular risk, stable patients with suspected coronary disease or with acute chest pain, in the preoperative evaluation of patients before noncoronary cardiac surgery and in the follow-up of cardiac transplant patients (25). CAC is an independent risk factor for the future cardiac ischemic events, stratification depending on its values. In a cohort with 4,4052 asymptomatic subjects, for a CAC reported as 0, 10-year risk of all-cause mortality was < 1% (26, 27). A CAC score ≥ 400 (Agatston units) indicate the subjects at high risk for future coronary events that should be referred for coronary angiography. However, absence of coronary calcium will not exclude the existence of noncalcified plaque (28).

Magnetic resonance is more valuable, but, at the same time, a more expensive imaging method of atherosclerosis. The use of this technique could bring new information about the remodeling of the arterial wall and vulnerable plaque in most of the arteries (coronary, carotid and peripheral arteries) and could serve as a reference point in monitoring therapy (29).

At the same time, some noninvasive, reproducible and safe tests have been developed for the assessment of the functional properties of the endothelium (brachial artery flow-mediated dilatation, pulse wave and contour analysis, pulse amplitude tonometry). The analysis of pulse wave velocity (PWV) is made by a device that calculates pulse wave propagation velocity between 2 arteries (carotid and femoral or radial) (30). Carotid-femoral pulse wave velocity > 12 m/s indicates an increased risk for future cardiovascular events.

Of the serum markers, C-reactive protein (CRP) or interleukin-6 are important for the expression of systemic inflammation and were correlated with cardiovascular events (31). Particularly CRP was introduced in different risk stratification models.

SOME PATHOGENIC HYPOTHESES

Usually, individual characteristics known as cardiovascular risk factors will influence the progression of atherosclerosis in time. Less evidence was collected about the pathogenesis of accelerated atherosclerosis in children, adolescents or young adults under the age of 45 years. Accelerated atherosclerosis was described in case of homozygous familial hypercholesterolemia (32). The disease is characterized by a genetic heterogeneity and a phenotypic variability with impaired functionality of the low-density lipoprotein (LDL) receptor, increased levels of LDL-cholesterol and lipoprotein (a), associated with low levels of high density lipoprotein cholesterol (HDL-cholesterol) (in some patients an accelerated turnover of HDL apoA-I and a decreased

HDL-cholesterol efflux could be present) (33). The current guidelines recommend Doppler echocardiographic evaluation of the heart and aorta annually and coronary CT every 5 years for the screening of subclinical atherosclerosis in children and young adults with familial hypercholesterolemia (33).

Epidemiological and clinical studies (34) also demonstrated a cluster of cardiovascular risk factors (hypertension, obesity, hyperglycemia, smoking, family history) in relationship with unhealthy lifestyle in these patients. Some of them meet the criteria for metabolic syndrome, namely insulin resistance, associated with increased risk of developing diabetes and cardiovascular diseases (5,35). Confounding factors could be present occasionally, in patients with thrombotic complications of some hereditary or acquired systemic diseases in the absence of significant atherosclerotic lesions. Early atherosclerosis in young women was particularly related to autoimmune processes or to high levels of lipoprotein (a) (36).

ELOQUENT STUDIES ON ATHEROSCLEROSIS IN YOUNG ADULTS

As mentioned above, the early development of atherosclerotic lesions in children and young adults was first documented in autopsy studies (2, 7). Although the atherosclerotic changes were demonstrated after death, in the Bogalusa Heart Study the approach was because the subjects were also followed-up before death for the description of cardiovascular risk factors and, partially, for the assessment of subclinical atherosclerosis by carotid ultrasound (6, 10, 37).

Vascular ultrasound and other validated methods for detecting subclinical atherosclerosis have permitted in vivo assessment of the atherosclerotic lesions. More clinical studies were published after 2,000 year and the most eloquent are presented below (tab. I).

TABLE I

The main clinical studies on atherosclerosis in young adult

Reference	Population (n)	Age range(y)/ Mean age (y)	Gender Male/Female (n)	Method for the assessment of atherosclerosis	Atherosclerosis outcome
1. Tuzcu et al. 2001 (1)	262	NR/ (33.4±13.2)	146/ 116	Intravascular ultrasound	Prevalence of atherosclerosis 52% in men and 51.7% in women, 17% in individuals < 20 years, 37% in age 20-29 years and 60% in age 30-39 years
2. Lee et al. (2007) (12) CARDIA Study	2,951, as part of the CARDIA Study	18-30 at CARDIA year 0/NR	NR	Computed tomography for CAC	Abdominal obesity was associated with early atherosclerosis
3. Mattsson et al. (2008) (5)	2,163	NR/ (32±5)	999/ 1,164	Ultrasound measurement of cIMT, and FMD	MS was associated with increased cIMT in both sexes

Reference	Population (n)	Age range(y)/ Mean age (y)	Gender Male/Female (n)	Method for the assessment of atherosclerosis	Atherosclerosis outcome
4. Knoflach et al. (2009) (36)	205	18-22/ 20.6±1	0/ 205	Ultrasound measurement of cIMT	Autoimmune processes, high lipoprotein (a), environmental exposure to tobacco smoke accelerated early atherogenesis in young women
5. Skilton et al. 2014 (38), Cardiovascular Risk in Young Finns Study	696	24-45/ 31.9±5	320/ 376	Ultrasound measurement of cIMT, and FMD	cIMT was increased in people with larger versus normal birth weight
6. Spring et al. 2014 (39), CARDIA Study	3,538, as part of the CARDIA Study	18-30 at CARDIA year 0/NR	1,535/ 2,003	Ultrasound measurement of cIMT, computed tomography for CAC	Healthy lifestyle changes during young adulthood are associated with decreased risk for subclinical atherosclerosis in middle age
7. Bhuiyan et al. 2015 (40), Bogalusa Heart Study	461, as part of the Bogalusa Heart Study	24-43/ 35.6	0/461	Ultrasound measurement of cIMT	cIMT was same in early menarcheal age (< 11 yrs.) vs normal menarcheal age (≥11yrs.) in white women but higher in black women
8. Eikendal et al. 2015 (41), USE-IMT initiative	3,067	NR/ 32-42	1,828/ 1,239	Ultrasound measurement of cIMT, recording of the new cardiovascular disease events	55 first-time myocardial infarctions or stroke occurred during a follow-up of 16,3 years and the events were related to cIMT
9. Reis et al. 2015 (42), CARDIA Study	4,061, as part of the CARDIA Study	18-30 at CARDIA year 0/NR	2,043/ 2,018	Recording of the new cardiovascular disease events	During a 24.8 year, median period of observation, were 125 incidents cardiovascular disease, 62 coronary heart disease and 33 heart failure events
10. Gidding et al. 2016 (43), CARDIA Study	3,008, as part of the CARDIA Study	18-30 at CARDIA year 0/NR	NR	Computed tomography for CAC and AAC	During the follow-up period, the CAC increased from 3 to 5 and AAC remain 2 between the age 35±3.6 to 40.2±3.6

Reference	Population (n)	Age range(y)/ Mean age (y)	Gender Male/Female (n)	Method for the assessment of atherosclerosis	Atherosclerosis outcome
11. Hartiala et al. 2016 (44), Cardiovascular Risk in Young Finns Study	589, as part of the Cardiovascular Risk in Young Finns Study	39-45/ NR	NR	Computed tomography for CAC	Mean levels of LDL-C, total cholesterol, Apo-B, and SBP levels across the 27-year period were significantly higher among those with CAC vs. those without
12. Eikendal et al. 2016 (45) The Atherosclerosis Risk in Young Adults (ARYA) Study	736	NR/ 28.4±0,9	344/ 392	Ultrasound for carotid intima-media echogenicity quantified as gray-scale median and for cIMT	Adolescent BMI related to cIMT and echogenicity in young adults; SBP only related to cIMT

AAC - abdominal aortic calcium, Apo-B - apolipoprotein B, BMI - body mass index,
CAC - coronary artery calcification, cIMT - carotid artery intima-media thickness,
FMD - brachial artery flow-mediated dilatation, LDL-C - low density lipoprotein cholesterol,
MS - metabolic syndrome, NR - not reported, SBP - systolic blood pressure

CONCLUSIONS

Our review has demonstrated an increased incidence of subclinical atherosclerosis in young adults. Based on the main selected studies, early atherosclerosis was related to a cluster of traditional risk factors (hypertension, obesity, hyperglycemia, smoking, dyslipidemia) and some non-traditional risk factors (birth weight), or more particular for the young women (lipoprotein (a), autoimmune processes). Further improvement in the methods of subclinical atherosclerosis assessment will consistently contribute to a better prediction of future cardiovascular morbidity and of outcome following the therapeutic strategies.

IS LIVER BIOPSY NECESSARY IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE? (Abstract): Nonalcoholic fatty liver disease is the most common cause of liver disease in the Western world. Liver biopsy is considered the gold standard in the diagnosis and progression of the disease and its usefulness cannot be neglected in terms of research. But in current clinical practice, liver biopsy tends to be replaced by less expensive and noninvasive methods allowing the identification of cardiovascular and metabolic risks. Given the fact that a small percentage of individuals with nonalcoholic fatty liver disease will progress to cirrhosis, attention will be focused more on cardiovascular risk as nonalcoholic fatty liver is now regarded as a distinct component of the metabolic syndrome. The aim of the clinician is to identify the early stages of fatty liver, using in this purpose simple and easily accessible methods. Many techniques have been proposed for the diagnosis of nonalcoholic fatty liver, from simple clinical factors (anthropometric indices measuring, blood pressure), laboratory biomarkers, imaging methods and scores, which should allow early treatment. This review describes different methods for identifying nonalcoholic fatty liver and various stages of this disease. **Keywords:** NAFLD, LIVER BIOPSY, NON-INVASIVE DIAGNOSIS

Nonalcoholic fatty liver disease (NAFLD) is a major problem of the 21st century and is the primary cause for liver disease in the western Europe. Even if it is generally benign, it can be associated with major hepatocellular impairment, inflammation and necroptosis, nonalcoholic steatohepatitis (NASH) being present in 20-30% of the subjects. Few of them will develop hepatic cirrhosis. Moreover, the issue of fatty hepatocytes goes further, because it increases the incidence of cardiovascular disorders and doubles the risk of diabetes mellitus, irrespective of the severity of hepatic impairment (1). Also, the cardiovascular risk is doubled by metabolic syndrome, and approximately one third of the subjects with NAFLD have metabolic syndrome (2).

Liver biopsy can be seen as a useful method for scientific research and liver disease staging. However, for the NAFLD patient, non-invasive and cheap methods are needed, which will allow the early diagnosis of the liver disease and the under-

lying cardiovascular risk.

NAFLD DIAGNOSIS

Currently, the available non-invasive methods for NAFLD diagnosis are represented by a set of symptoms and signs, and a combination of clinical and laboratory tests. Although some of these markers are usually useful for diagnosing an NAFLD patient, they do not have a high specificity and sensitivity capable of distinguishing between NAFLD and NASH and determining the degree of fibrosis.

Liver biopsy is currently the gold standard for NAFLD diagnosis because it allows the exclusion of different causes of liver injury and it can estimate the severity of adipose infiltration in the liver, inflammation of the lobes, hepatocyte ballooning and fibrosis. Even though it is the gold standard, liver biopsy has some limits; it is an invasive procedure, it is associated with certain risks and its analysis can be influenced by pathologist's subjective judgment (3).

An important issue that requires mentioning is the quality of non-invasive methods compared to liver biopsy for diagnosing NASH. Currently, the available non-invasive methods for NASH diagnosis are represented by signs and symptoms, biochemical tests and combinations of physical examination and laboratory tests. Once the NAFLD diagnosis is made, its severity should be assessed, which is useful to predict the disease course. When determining the NAFLD stage, 2 factors are related to severity: degree of fibrosis and of inflammation (4).

Physical examination is non-specific for assessing the severity of NAFLD. The conditions usually associated with the severity of this disease include obesity, old age, diabetes mellitus and high blood pressure.

Typical biomarkers – only one biomarker cannot diagnose NAFLD or differentiate among steatohepatitis, NASH or liver cirrhosis. Even though a slightly elevated serum aminotransferase level is the first change noted in NAFLD patients, the transaminases are within normal ranges in most of these subjects. Moreover, all the histologic changes seen in NAFLD subjects may be associated with normal transaminases. Serum gamma-glutamyl transpeptidase (GGT) is usually elevated in NAFLD subjects and is reportedly associated with increased mortality. Despite this, the diagnosis of NAFLD cannot be made solely based on GGT levels (5).

Inflammation – a proinflammatory status typical to metabolic syndrome was shown to be related with the course of steatohepatitis and liver damage in NAFLD. Inflammatory markers may also have a diagnostic potential. A study (6) described a relationship between cytokine level and NASH. Moreover, the level of TNF-alpha correlates with the degree of inflammation and fibrosis. It has been found that adiponectin level is notably lower in the early stage of NASH as opposed to simple steatosis. Another study (7) reported a relationship between leptin, hormone produced in the adipose tissue, and the histologic appearance of hepatic parenchyma. Hyaluronic acid (HA) and CC-chemokine ligand 2 (CCL-2), which are also markers of inflammation, were also proved to be elevated in NASH subjects.

Fibrosis – Markers of fibrosis are represented by HA and type IV 7s collagen. In a study of 112 NAFLD subjects it has been noted that these 2 biomarkers could exclude late stages of fibrosis. In NAFLD patients, assessing HA levels has proved to be helpful in predicting advanced stages of fibrosis (8).

Hepatocyte apoptosis – has a major role

in liver damage in NAFLD subjects. Lately, a particular product of liver cell apoptosis, caspase–cleaved fragments of Cytokeratin 18 (CK18) have proved to be significantly elevated in NASH patients, compared to steatosis patients or healthy subjects. Moreover, it has been shown that the serum CK18 level, measured by ELISA test, was significantly higher in NASH patients, compared to controls and steatohepatitis patients. CK18 proved to be a predictor of NASH. NASH patients who underwent metabolic surgery, procedure which was shown to have a favorable effect on BMI, had lower CK18levels (9).

NON-INVASIVE METHODS

Regarding biomarkers, different scores have been proposed in order to recognize NAFLD.

SteatoTest - is a mix between FibroTest (which is a marker of fibrosis in patients with hepatitis B or C and alcoholic liver disease) and ActiTest (surrogate marker of hepatocyte necrosis in hepatitis B and C) and body mass index (BMI), triglycerides, cholesterol and blood sugar levels, adjusted for gender and age (10).

Fatty liver index (FLI) (11) is a mixed method based on four parameters: waist circumference, BMI, triglycerides and GGT, which allows the prediction of fat deposition in the liver with an 84% certainty. The score was initially used to diagnose subjects at high risk of steatosis, who needed ultrasonography and lifestyle changes; then it was certified as marker of prognosis, used to predict the intima media thickness, coronary diseases, insulin resistance, but also the nine-year incident diabetes and atherosclerosis (12).

Lipid accumulation product (LAP) is calculated using the waist circumference and the serum triglyceride levels; it was reported as a predictor for the risk of diabetes, cardiovascular diseases and mortality of all cause in patients with high risk of cardiovascular disease. The natural LAP logarithm, adjusted for gender, has a sufficient accuracy in recognizing subjects with liver steatosis who need ultrasonography (13).

HAIR Score – is useful for predicting NASH in patients suffering from severe obesity (BMI>35kg/m^2). This score is based on 3 factors; their presence being scored 1 point each: 1. Hypertension: 1 point; 2. ALT> 40UI/L: 1 point; 3. Insulin resistance index >5.0: 1 point. The total score is obtained by summing the scores for the 3 factors. A HAIR score of 3 practically confirms NASH (14).

BAAT Score – the presence of only one of the factors below rules out septal fibrosis and liver cirrhosis: 1. BMI>=28kg/m^2: 1 point; 2. Age >=50: 1 point; 3. ALT (alanine aminotransferase) >= 2x (normal value): 1 point; 4. Triglycerides>=1.7mmol/L (150mg/dl): 1 point. A final score of 1 or 0 has a negative prognostic value of 100% for fibrosis (sensitivity 100% and specificity 46%) (15).

NICE Model - is based on the presence of the metabolic syndrome (using International Diabetes Federation criteria), ALT levels and caspase-cleaved CK18 fragment levels (assessed through biopsy). A score of over or equal to 5 allows for the accurate diagnosis of NAFLD in patients with morbid obesity (16).

NASH Score System for Morbidly Obese - consists of 6 parameters, namely obstructive sleep apnea, type 2 diabetes, hypertension, ALT>=27U/L, AST >=27U/L and Caucasian race. Two points are assigned to Caucasian race and one point is assigned to the rest of the five components. The probability of NASH is determined based on the summed points (17). Another study (18) reported that approximately 90% of the

patients with early-stage NASH could be predicted by assessing the serum adiponectin level, serum type IV collagen 7S level and insulin resistance. Resistin and adiponectin are synthesized especially in fat tissue and play a major role in insulin resistance. Low levels of adiponectin are present in NAFLD patients.

IMAGING METHODS

Imaging methods cannot make the difference between NASH and steatosis, but the diagnosis they provide orient therapy designed to reduce the cardiovascular risk.

Ultrasonography - is an available, non-invasive and cheap method used to detect hepatic steatosis; its specificity is 66-95% and sensitivity 60-94%; the assessment of liver steatosis is subjective, on a three-point scale (severe, moderate and intermediate) (19).

Computed tomography (CT) - permits a better analysis, superior to ultrasound, by measuring the mean liver attenuation in Hounsfield units (HU), but there is variability in interpreting hepatic attenuation on CT scans (19).

Magnetic resonance imaging (MRI) – for assessing liver steatosis two methods can be used: magnetic resonance imaging (MRI) and proton magnetic resonance spectroscopy (H-MRS). MRI has a 100% accuracy in detecting liver steatosis. Even though it is a highly accurate method for detecting and dynamically quantifying steatohepatitis, it is expensive and not readily available (20).

Elastography (Fibroscan) – Multiple meta-analyses suggest that liver stiffness measurement using Fibroscan is a useful method for the evaluation of early stages of cirrhosis and severe hepatic fibrosis.

Acoustic radiation force impulse (ARFI) – is a method by which the elastic properties of a surface are evaluated, giving real-time images in mode B. Unlike elastography, this method is not restricted to subjects with high BMI (21).

Magnetic resonance elastography – method used to study the elastic properties of an area of interest in the liver tissue (22).

CONCLUSIONS

Due to the high prevalence of NAFLD, we believe that cheap and non-invasive methods are needed in order to diagnose this hepatic impairment. Liver biopsy, regarded as the “golden standard”, has few benefits for patients (especially those with early-stage NAFLD who are more at risk of cardiovascular disease than hepatic complications); it is useful, however, in medical research, even if the ethical aspect remains a matter of debate.

We conclude that non-invasive methods (risk scores, biomarkers and imaging methods) can replace liver biopsy in early stages of NAFLD. Further studies are required to validate new non-invasive diagnosis methods.

INFLUENCE OF SLEEP ON OBESITY IN CHILDREN (Abstract) Childhood obesity is a global epidemic with long term implications. The main cause of obesity is an increase in calorie intake and a decrease in physical activity, but also there is clear evidence suggesting a link between the duration and quality of sleep and obesity risk. Good sleep habits are involved in increased ability to concentrate at school, improvement of general state, immune system development, increased quality of life. On the other hand, there are several mechanisms by which chronic sleep deprivation induces weight gain: disturbance of hormones that control hunger center, increased time for meals, reduced physical activity, metabolic changes. Recently, nighttime sleep duration has declined, in contrast with the increasing prevalence of obesity. Childhood sleep habits have a long term effect on weight, with repercussions even into adulthood. This is the reason why there is increasing interest to include sleep quality on the list for childhood obesity prevention. Sleep represents an important and independent risk factor of obesity in children and adolescents and it should be taken into consideration in the management of obesity. **Keywords**: OBESITY, SLEEP, CHILDREN

Childhood obesity is a global epidemic with long-term implications: cardiovascular diseases (high blood pressure, dyslipidemia), endocrine dysfunctions (diabetes type 2, insulin resistance), pulmonary complications (obstructive sleep apnea, asthma, effort intolerance) (1). Recent statistical studies have shown that the prevalence of obesity increased dramatically, particularly in boys, and especially in rural areas (2). Considering all these aspects, special attention should be paid to risks factors and prevention of childhood obesity.

It is well known that the main cause of obesity is an increased calorie intake in combination with decreased physical activity (3). But it is widely accepted that other significant factors are also involved in this process. Thus, literature data show convincing evidence that shorter sleep duration and poorer sleep quality is an important and independent risk factor of obesity in children (4).

BENEFITS OF SLEEP

In order to understand the consequences of sleep deficit, we must first know the benefits of a quality sleep. Good sleep habits are involved in increased ability to concentrate at school, improvement of general state, immune system development, increased quality of life. Along with diet

and exercise, sleep plays an important role in growth, development and maturation of body functions, especially during childhood, when more sleep is needed than in adulthood. Adequate sleep also plays a key role in the regulation of homeostasis and hormonal systems involved in somatic and intellectual development, brain maturation, information processing and memory consolidation (5, 6, 7).

Insufficient sleep has been linked to emotional, social, cognitive and behavioral disturbances, such as poor concentration, depression, unsatisfactory academic results, suicidal tendency. All these negative effects improve with increased sleep duration both in childhood and adolescence (8).

HOW SLEEP AFFECTS BODY WEIGHT

Besides all these benefits, sleep plays a role in body weight. To better understand this mechanism a series of studies and researches have been conducted. Their conclusion was that lack of sleep increases the appetite because it influences the hormones regulating the hunger center. Among these hormones are leptin and ghrelin. Leptin is considered a marker of energy stores. Low leptin levels signal the nervous system of a depletion of energy reserves, which leads to increased appetite. On the other hand, ghrelin, the hormone released by gastric cells, is a marker of energy deficit. So, higher ghrelin levels stimulate the appetite and storage of ingested calories (9). There are studies which show that sleep deprivation increases ghrelin level and decreases the leptin level with a corresponding increase in hunger and appetite, especially for foods rich in fats and carbohydrates (10).

Another element through which sleep influences body weight is the availability of more time for meals. People who sleep less at night will consume more food than people with normal sleep duration, because they have more time available to think about food. Sleep also influences physical activity. People who do not get enough sleep are tired and therefore will reduce the exercise duration. Sleep-deprived people tend to spend more time watching television and less time in playing sports (11, 12). Laboratory experiments show that sleep deprivation lowers body temperature, which leads to lower energy consumption and finally to accumulation of extra weight (11, 13).

The reduction of sleep duration produces metabolic changes in the body. There are several hormones that fluctuate during the light/dark cycle, being affected by sleep: growth hormone, melatonin, cortisol (14). Sleep deprivation is associated with a decline in glucose tolerance and insulin sensitivity, which effectively prevents the body to metabolize sugar from food (15). It was also found that short sleep duration is associated with a pre-sleep growth hormone secretion in addition to the normal hormone secretion (6, 16). These increased growth hormone levels may induce a transient insulin resistance in muscle tissue, resulting in a significant increase of insulin resistance in other tissues (17). Also, elevated evening cortisol concentrations are likely to result in reduced insulin sensitivity on the following morning (6, 17). Other complications associated with insulin resistance and obesity in childhood and adolescence include metabolic syndrome, fatty liver and polycystic ovary disease (18).

In addition, sleep deprivation could decrease energy expenditure by reducing the thyroid stimulating hormone (TSH), and

this fact has as consequence a reduced rate of the basal metabolism or a disturbance of neural circuits which control body weight (14).

IMPACT OF SLEEP ON CHILDHOOD OBESITY

Recently, night time sleep duration has declined, in contrast with the increasing prevalence of obesity. It has been shown that when children aged 10-17 years were offered optimal sleep conditions for several days in a raw, they used to sleep an average of 9 hours/day. This demonstrates that the body needs at least 9 hours of rest per day. In contrast with these physiological needs, the statistics show that teenagers get 7 hours of sleep or less (5, 6, 7). Also, over the past century sleep duration decreased by 0.75 minutes per year, with a more significant decrease on school days, for older children, and especially for boys (19).

Studies aimed at illustrating the effect of sleep deprivation on body weight in children have been conducted. Thus a British study in over 8000 children measured weight, height and body mass index. Other risk factors probably involved in obesity, such as maternal education, intrauterine and perinatal factors, food habits, family and demographic characteristics were also considered. The results showed that sleep is an independent risk factor, children getting less than 10.5 hours/night of sleep at age 3 having a 45% higher risk of obesity at age 7 compared to those getting at least 12 hours/night (4). Similarly, a study in 915 US children aged 6 months, 1 year and 2 years aimed at predicting the effects of sleep duration on body mass index (BMI), subscapular and triceps skinfold thicknesses, and overweight. The conclusion was that an average daily sleep duration of less than 12 hours during the first year of life increases by 2 times the risk of obesity at age 3 (20).

Childhood sleep habits have a long term effect on weight, with consequences well into adulthood. This was demonstrated by a study on over 1000 children from New Zealand, followed from birth until age 32 using information on the hours of sleep at age 5, 7, 9 and 11 years. It has been shown that each 1 hour reduction in sleep duration during infancy is associated with a 50% higher risk of obesity at the age 32 (21). Furthermore, late bedtimes and late wake up times are associated with an unfavorable weight status profile, both in children and adults, regardless of gender (22).

GOOD SLEEP HABITS

Regarding the optimal duration of sleep to be recommended to parents for their children, the body needs change as the child grows from infancy up to childhood and adolescence. The sleeping duration recommendations of the American Sleep Foundation are: 0 – 3 months: 14 – 17 hours/day; 4 – 11 months: 12 – 15 hours/day; 1 – 2 years: 11 – 14 hours/day; 3 – 5 years: 10 – 13 hours/day; 6 – 13 years: 9 – 11 hours/day; 14 – 17 years: 8 – 10 hours/day; 18 – 25 years: 7 – 9 hours/day (23).

To effectively advise parents of overweight children, it is important to investigate aspects related to duration and quality of sleep, in order to assess whether they get enough sleep, difficulty awakening in the morning, drowsiness or excessive daytime fatigue associated with concentration difficulties at school or with homework, difficulties in putting the child to sleep at night, systematic nigh awakenings. All these elements indicate the existence of sleep

problems. In this case, it is important to correct children′s sleep issues, which can prevent both obesity and related health consequences.

Some recommendations for a better quality sleep are:

- Follow a regular sleep schedule (go to bed and wake up the same time every day);
- Relaxing activities before bedtime;
- Avoid television, computer use or video games at least 3 hours before bedtime
- Avoid before bedtime heavy food as well as foods and beverages with stimulating effect such as chocolate, caffeine containing sodas (24, 25).

CONCLUSIONS

In conclusion, sleep is an important and independent risk factor of obesity in children and adolescents. Even though obesity prevention is based on nutrition and physical exercise, sleep habits should be also taken into consideration for a more efficient management of obesity. A healthy sleep implies enough hours of restorative sleep, without interruptions (to be able to pass through all stages of sleep), adapted to the sleep needs of each period of childhood, and suitable to the natural biological rhythm of the child. Once learned the discipline of a quality sleep, the child has a better compliance regarding food and physical exercise discipline. Considering all the chronic medical complications that obesity can cause, we can strongly affirm that a healthy sleep is one of the keys to maintaining a normal weight, contributing to a healthier life both now and in the future.

NADPH OXIDASE: STRUCTURE AND ACTIVATION MECHANISMS (Review). NOTE I (Abstract) NADPH oxidase (nicotinamide adenine dinucleotide phosphate-oxidase), with its generically termed NOX isoforms, is the major source of ROS (reactive oxigen species) in biological systems. ROS are small oxygen-derived molecules with an important role in various biological processes (physiological or pathological). If under physiological conditions some processes are beneficial and necessary for life, under pathophysiological conditions they are noxious, harmful. NADPH oxidases are present in phagocytes and in a wide variety of nonphagocytic cells. The enzyme generates superoxide by transferring electrons from NADPH inside the cell across the membrane and coupling them to molecular oxygen to produce superoxide anion, a reactive free-radical. Structurally, NADPH oxidase is a multicomponent enzyme which includes two integral membrane proteins, glycoprotein $gp91^{phox}$ and adaptor protein $p22^{phox}$, which together form the heterodimeric flavocytochrome b558 that constitutes the core of the enzyme. During the resting state, the multidomain regulatory subunits $p40^{phox}$, $p47^{phox}$, $p67^{phox}$ are located in the cytosol organized as a complex. The activation of phagocytic NADPH oxidase occurs through a complex series of protein interactions. **Keywords:** REACTIVE OXYGEN SPECIES, NADPH OXIDASES, NOX, STRUCTURE, LOCALIZATION, FUNCTIONS.

Oxidative stress (SO) is essentially the result of an imbalance between the endogenous production of free radicals derived from oxygen (ROS) or nitrogen (RNS), and the ability of the body to counteract or detoxify their harmful effects through neutralization by antioxidants (1, 2, 3). This molecular imbalance in ROS metabolism has been proven both at the cellular level and throughout the body. ROS have an opposing, context-depending dual role.

Under normal circumstances, the production and removal of ROS, that occurs in distinct extracellular or (sub)cellular spaces, are strictly controlled by effective endogenous defense mechanisms that block their excessive production. Some reactive oxygen species are necessary for life (especially superoxide anion radical O^{2-}, hydrogen peroxide H2O2) (4) having a pivotal role in mediating important functions in normal cellular physiology by their contri-

bution to regulating different physiological processes such as cellular defense, signaling mechanisms, steroid synthesis, activation of G protein-coupled receptors, regulation of transcription factors, gene expression (5).

Overproduction of ROS results in oxidative stress with various pathological consequences such as atherosclerosis, hypertension, vascular remodeling after angioplasty, myocardial infarction, asthma, stroke, etc. (6, 7, 8, 9).

Sources of ROS. Of the many sources of ROS we mention the redox enzymes NADPH oxidase, mitochondrial respiratory chain, xanthine oxidase, lipoxygenase, and cyclooxygenase, which are continuously interacting with each other. In biological systems, ROS have the superoxide radical anion O^{2-} as one of the most important representative. A typical enzyme belonging to this redox group that generates ROS is NADPH oxidase, with important biological functions (10). NADPH oxidases are present in the higher life forms (animals, plants), but also in fungi, but not in prokaryotes and most unicellular eukaryotes. The enzyme is expressed in professional phagocytic cells, multiple types of blood cells (such as neutrophils, monocytes, eosinophils, macrophages, mast cells) (11) involved in antibacterial, antifungal, antimicrobial defense by reactions with free radicals; the enzyme is also involved in innate immunity (12). Phagocytic NADPH oxidase becomes active upon stimulation and then generates superoxide anions. An alternative scenario in that phagocytic NADPH oxidase directs the ions inside and outside the vacuole formed by endocytosis producing changes in pH and ion flow (13). NADPH oxidase and NADPH oxidase-like enzyme also described in non-phagocytic cells have been identified in almost every type of tissue, but functionally distinct from phagocytic oxidases (14). Non-phagocytic NADPH oxidases are constitutively active enzymes that produce superoxide radical anion intracellularly in a slow and sustained manner and act as a signaling molecule influencing the transcription factors, molecules involved in inflammation, cell growth etc (15).

The cellular compartments in which NADPH oxidases are expressed include: the nucleus, endoplasmic reticulum, endosomes, phagosomes, mitochondria, and extracellular space (16).

Structure of NADPH oxidase. In mammals, NADPH oxidase is a plasma membrane-bound multicomponent complex (heteroprotein) that faces the extracellular space, consisting of 7 isoforms (homologues). ROS is produced by NADPH oxidase through NOX protein, thus differentiating the enzyme from other oxidases. NADPH oxidases are collectively referred to as the NOX family: NOX 1, NOX 2 (identical to membrane glycoprotein $gp91^{phox}$, also known as a subunit β, suffix phox refers to **ph**agocyte **ox**idase) (17), NOX 3, NOX 4, NOX5 and associated dual oxidases – Duox 1 and Duox 2 (18, 19, 20). The catalytic subunits of NOX 1, NOX 2, NOX3 and NOX 4 form a macromolecular complex with $p22^{phox}$ (known as subunit α) as a common enzyme activator subunit. NOX 5 Duox1 and Duox2 are $p22^{phox}$-independent isoforms. Duox 1 and 2 have additional peroxidase domains termed this way due to homology to peroxidases which catalyze dismutation of superoxide anion to hydrogen peroxide – H2O2 (13). Therefore, each of these isoforms has a core catalytic

subunit, the so-called NADPH-oxidase (NOX), two dual oxidase subunits (Duox) and 5 regulatory subunits.

Isoenzymes of NADPH-oxidase (NOX) are distinguished by the following features: subcellular localization, tissue and subcellular patterns of expression, structure (the nature of the catalytic subunits determines the adaptation of regulatory subunits), mechanism of enzyme activation, ROS-generating catalytic mechanism and functions (1, 10,21).

Physiological functions of NADPH oxidases: the enzymes catalyze the transfer of electrons in cytosol across the membrane from NADPH, which oxidizes, to molecular oxygen, which is reduced to produce the superoxide radical anion (O^{2-}), generator of other ROS species. The NADPH oxidases was originally identified as a component of innate host defence. In phagocytes, this complex enzyme is activated to produce superoxid anion and other secondarily derived ROS, wich promote killing of invading micro-organisms. Another non phagocytic NADPH oxidases system is present in almost every body organ being physiologically involved in signal transduction, cell proliferation and differentiation, posttranslational processing of proteins (4, 18).

Mechanism of action of NADPH oxidase Although all NOX enzymes have the same function in ROS generation, the activation and control mechanisms, the nature of the ROS produced, subunit requirements, and intracellular distribution varies between isoforms (22). Some NOX are membrane proteins with catalytic functions, other have cytosolic localization and regulatory functions (23). All NOX family members share a common core structure made up of 6 transmembrane domains. The catalytic core of the classic phagocytic enzyme – NADPH-oxidase (NOX 2) as of the other isoforms consists of two membrane-integrated proteins (subunits): $gp91^{phox}$, glycosylated protein (24), (considered the patriarch of NOX family) and $p22^{phox}$ (non-glycosylated adapter protein) which together form a large subunit, the flavocytochrome b558 complex (heterodimeric flavohemoprotein b558). $Gp91^{phox}$ subunit consists of 6 transmembrane domains and the cytoplasmic C-terminal region which contains two binding sites for FAD (flavin adenine dinucleotide) and for the electron donor NADPH. All NADPH oxidases except NOX 5, Duox 1 and Duox 2 have similar topological structure of the catalytic core $gp91^{phox}$. The N-terminal domain of NOX 5 binds calcium, Duox1 and Duox 2, in addition to the NOX 5 structure present at the N-terminal transmembrane α-helix a domain homologous to peroxidase (25).

The regulatory subunits play important roles in: maturation and expression of NOX and Duox subunits in biological membranes, and in enzyme activation and spatial organization of the various components of the enzyme complex (26). Some isoforms of NADPH oxidase contain GTP-ase (guanine triphosphate hydrolase), Rac 1 and Rac 2, which modulate their activity (27).

The activation of phagocyte NADPH oxidase occurs through a series of complex protein interactions in response to numerous agonists (27). In unstimulated cells, components $p40^{phox}$, $p47^{phox}$ and $p67^{phox}$ are grouped in the cytosol into a complex (25).When the resting cell is exposed to a variety heterogeneous stimuli (chemical, physical, environmental, biological factors)

(24), the peripheral cytosolic component becomes highly phosphorylated able to form a complex which migrates to the membrane where it associates with flavocytochrome b558 and together with other components – $p40^{phox}$, $p47^{phox}$ and $p67^{phox}$ – forming the active oxidase which transfers electrons from the substrate (NADPH) to molecular oxygen with formation of superoxide radical anion (27, 28), precursor of other toxic ROS (17). The activation process is strictly controlled, involving in addition to phosphorylation multiple conformational changes. This enzymatic complex is involved in many key biological functions such as cell growth, proliferation, differentiation, migration, defense, signaling and regulation of gene expression. Excessive ROS production attributed to the increased NOX activity, causing cellular oxidative stress, may contribute to the occurrence of a wide variety of diseases: vascular disease, inflammation, endothelial dysfunction, cell proliferation, fibrosis, angiogenesis, cardiovascular remodeling, cardiac aging, renal remodeling in hypertension, atherosclerosis, diabetes, heart failure, myocardial ischemia-reperfusion injury.

CONCLUSIONS

NADPH-oxidases is a proteic complex that, being stimulated, is capable to produce O^{2-}, by transfering an electron from NADPH to O2. It is a multicomponent family enzyme, with a complex structure made of membrane proteine complex, with cathalitic properties; in the same time, the enzyme has citosolic structures with regulatory properties. The tisulary distribution of NADPH-oxidases and their activating mechanisms are of large variety.

LEVELS OF MUTANS STREPTOCOCCI AMONG SCHOOLCHILDREN IN IASI, ROMANIA (Abstract): **Aim:** To evaluate the dental and salivary density of *mutans streptococci* among Iasi schoolchildren. **Material and methods**: This study cross-sectional included 533 schoolchildren aged 7-12 years. The density of *mutans streptococci* on dental surface (mesial and occlusal surfaces of teeth 1.6 and 3.6) and in saliva was assessed using Dentocult® SM Strip mutans kits (Orion Diagnostica Oy) according to manufacturer's instructions. Subjects were given one of the following scores: 0 = $<10^4$ CFU/ml; 1 = $<10^5$ CFU/ml; 2 = 10^5–10^6 CFU/ml; 3 = > 10^6 CFU/ml. **Results**: A *mutans streptococci* density score 3 was predominant both in saliva and on the mesial and occlusal surfaces of the first permanent molars. Scores 2 and 3 were predominant in younger children, while in 12-year-old children the four scores were in similar percentages**. Conclusion**: High levels of *mutans streptococci* prevail among Iasi schoolchildren, highlighting the need to implement complex caries prevention programs. **Keywords**: SCHOOLCHILDREN, MUTANS STREPTOCOCCI, DENTAL CARIES.

Oral diseases are the result of a complex interaction between etiologic factors and a number of risk factors, modulated by protective factors. Pointing out the risk factors enables the identification of those elements that act to damage oral health, which further makes possible the implementation of measures aimed at eliminating the action of these factors.

Detailed and accurate knowledge of the distribution of oral diseases and their determinants in the population is a compulsory stage for developing strategies to improve preventive programs and planning dental services.

The aim of the present study was to evaluate the dental and salivary density of *mutans streptococci* (*MS*) among schoolchildren in Iasi town.

MATERIAL AND METHODS

The study was cross-sectional, clinical and microbiological and was conducted in 2014. The study sample was selected according to the following criteria: children aged 7 to 12 years, attending schools in various districts of Iasi town; schools that have a dental office. The sample was selected using the probabilistic method and included 533 children (50.47% males and 49.53% females).

Examinations were performed in the

dental offices in schools.

The density of *MS* on dental surface (mesial and occlusal surfaces of teeth 1.6 and 3.6) and in saliva was assessed using Dentocult® SM Strip mutans kits (Orion Diagnostica Oy) according to manufacturer's instructions. For the assessment of dental density, special tips were used to take bacterial plaque samples; these were subsequently spread on the four sites of the square-tipped strips. For salivary density evaluation, the patient was invited to chew a paraffin pellet for 1 minute, in order to facilitate the transfer of *MS* from tooth surfaces into the saliva; the patient was instructed to eliminate any excess saliva, then the rough surface of the round-tipped strip was pressed against the saliva remaining on patient's tongue. The two strips (with dental and salivary samples) were then placed, with the smooth surfaces clipped and attached to the cap, in the selective culture broth; the vials were labeled with patient's data, then incubated at 35-37°C for 48 h; after incubation, the strips were removed from the culture broth and dried, then the density of the grown colonies was compared to the chart provided by the producer, according to the following scores: 0 = $<10^4$ CFU (colony-forming unit)/ml; 1 = $<10^5$ CFU/ml; 2 = $10^5 – 10^6$ CFU/ml; 3 = > 10^6 CFU/ml.

Tests were performed at least 1 h after eating and toothbrushing, in a separate dental visit and not during a treatment session; patients on antibiotic therapy during the last month before testing were excluded.

Written parental consent for children participation in the study was first obtained. Children also had the opportunity to accept or refuse participation.

Data privacy as well as the impossible identification of subjects in the case the results are published were ensured.

SPSS 17.0 was used for statistical analysis of data. The statistical significance threshold p was set at 0.05; chi-square test was used for data comparison and correlation analysis was performed using Spearman test.

RESULTS

Evaluation of data obtained after performing bacteriological tests to determine the dental density of *MS* showed that score 3 (that is a density of more than 10^6 CFU/ml) was predominant on both the mesial and occlusal surfaces of teeth 1.6 and 3.6 (tab. I).

Analysis of frequency distribution showed that scores 2 and 3 cumulated were present in more than half of the subjects.

TABLE I

Children distribution (%) depending on *mutans streptococci* scores on dental surfaces

Score	Situs			
	Mesial surface 1.6	***Mesial surface 3.6***	***Occlusal surface 1.6***	***Occlusal surface 3.6***
0	23.52	23.49	23.10	23.04
1	12.44	12.62	12.21	13.14
2	30.76	31.45	24.05	28.42
3	33.28	32.44	40.64	35.40

At the same time, however, it is to note that only 23% of the children included in the study presented a dental density of *MS* of less than 10^4 CFU/ml.

Separate analysis by age group (tab. II) showed that nearly half of the 7-year-old children presented a dental density of *MS* of more than 10^6 CFU/ml.

TABLE II

Distribution (%) of *mutans streptococci* dental scores by age group

Score	Age (years)					
	7	*8*	*9*	*10*	*11*	*12*
0	16.4	17.2	17.8	19.5	21.8	22.1
1	4.7	7.2	17.3	23.6	24.1	26.3
2	36.8	35.2	33.7	29.8	28.2	27.7
3	42.1	40.4	31.2	27.1	25.9	23.9

Score 3 on dental surfaces remained predominant at the age of eight; in children aged 9 and 10 years score 2 became predominant, then the differences between scores attenuated, so at age 12 the four scores presented similar percentages.

Chi-square statistical test indicated that the differences between age groups in the distribution of *MS* dental scores were statistically significant ($p < 0.01$), and Spearman correlation coefficient indicated a weak, inverse correlation: scores decreased with increasing age ($r = -0.20$).

Assessment of *MS* salivary density showed that score 3 was predominant in this case, too (32.54%); as with dental surfaces, scores 2 and 3 cumulated were present in more than half of the investigated subjects (tab. III).

At the same time, however, it is worth mentioning that less than a quarter of the children aged 7-12 years (23.63%) presented a salivary density of *MS* lower than 10^4 CFU/ml.

The age distribution was similar to the one on dental surfaces: at the age of 7, score 3 was predominant (50.1%), as well as at the age of 8 (43.5%); after that, the distribution of scores tended to become uniform, so at the age of 12 years the four scores presented similar percentages.

Statistical analysis revealed statistically significant differences ($p < 0.01$) between age groups regarding the distribution of *MS* salivary scores; Spearman correlation coefficient indicated a weak, inverse correlation between age and the salivary level of *MS* ($r = -0.189$).

TABLE III

Distribution (%) of *mutans streptococci* salivary scores by age group

Score	Age (years)						Total per sample
	7	*8*	*9*	*10*	*11*	*12*	
0	16.3	17	31.5	27.8	25.6	23.5	23.63
1	2.4	6.3	11.3	13.4	19.4	23.5	13.01
2	31.2	33.2	30.9	38.4	28.5	23.4	30.82
3	50.1	43.5	26.3	20.4	26.5	29.6	32.54

DISCUSSION

The role of *mutans streptococci* in initiating carious lesions is very well known today. The predominance of the highest score, meaning a density of more than 10^6 CFU/ml, both on the mesial and occlusal

surfaces of the first permanent molars, is an important factor of an unfavorable distribution of children into caries risk groups.

In addition, score 0, although found in about 23% of the children both in saliva and on dental surfaces, does not always mean that the patient is completely free from *mutans streptococci*, but signifies a density of less than 10^4 CFU/ml. For this reason, the prevalence of *mutans streptococci* can be considered to be high among the examined children.

However, a similar distribution of schoolchildren by the level of *mutans streptococci* was recorded in many other countries. Thus, in Sweden, a prevalence of 76% of this bacterial species was found among children aged 9 years, while in Israel 52.1% of the 12-year-old children presented the highest score for *mutans streptococci*, and only 5.4% the lowest score (1).

Studies in Turkey demonstrated that most of the children aged 7-9 years presented scores 2 and 3 of *mutans streptococci* salivary levels (2).

Data from studies conducted in Italy showed that more than 25% of the children aged 7-9 years presented a salivary density of *mutans streptococci* of at least 10^5 CFU/ml (3), while in India the prevalence of *mutans streptococci* in children aged 13 years was 87.37%, and 33.87% of them presented high levels of this bacteria (4).

One of the important features in *mutans streptococci* ecology is the localized growth manner. While some tooth surfaces may be carriers of *mutans streptococci*, other surfaces, located right in the neighborhood, may not have these microorganisms. Experimental studies have shown that surfaces colonized with *mutans streptococci* are at higher caries risk than non-colonized surfaces. However, their simple presence on a dental surface that does not necessarily mean that caries will develop on that surface, but signifies an increased risk of caries occurence (5).

In this regard, studies have shown a significant correlation between the level of *mutans streptococci* and carious lesions on permanent teeth (6, 7, 8).

Studies that have examined the influence of fluoride mouthrinses on *mutans streptococci* count showed that the use of these solutions clearly determined a decrease of their salivary level (9, 10, 11, 12).

As to the influence of dental sealants, although they obviously reduce the development of fissure caries, their application is not always followed by a reduction in the salivary level of *mutans streptococci*, because the sealant may itself be colonized on the external surface (13).

The literature provides evidence suggesting that in children the risk of caries is greater the earlier the contamination with *mutans streptococci* occurs, although this risk may be partially compensated by other factors, including good oral hygiene and non-cariogenic diet. Moreover, nutrition and oral hygiene can counterbalance each other, so that carious lesions can be controlled even in the situation of a cariogenic diet, with the condition of maintaining a rigorous oral hygiene (14, 15, 16, 17).

CONCLUSION

The results of the present study show a high prevalence of elevated levels of *mutans streptococci* among Iasi schoolchildren, underlining the need for complex prevention programs in children, that should include multiple methods for the primary prevention of dental caries.

EXTRAHEPATIC MANIFESTATIONS IN CHRONIC HEPATITIS B – THE EXPERIENCE OF THE IASI INFECTIOUS DISEASES HOSPITAL BETWEEN 2012-2014 (Abstract): There are numerous extrahepatic syndromes associated with HBV infection: vascular, renal, and cutaneous manifestations, essential mixed cryoglobulinemia, and neurological phenomena. **Aim:** This study proposes an approach to the extrahepatic manifestations of chronic hepatitis B as it has been shown that the persistent production of immune complexes induces extrahepatic lesions. **Material and Methods**: In the interval 2012-2014 180 cases of chronic hepatitis B were admitted to the Iasi Infectious Diseases Hospital. **Results:** The mean age of the study patients was 41 years, most patients being male (65%) and living in urban areas (70%). Cutaneous manifestations of chronic HBV infection were present in 62% of patients and consisted in: rash (25%), Gianotti-Crosti syndrome (15%), cryoglobulinemia (21.11%) and Henoch-Schonlein purpura (12.22%). Panarteritis nodosa (PAN) with a prevalence of 9%, and renal manifestations -glomerulonephritis (2.77%) and nephrotic syndrome- were present. Also reported were neurological manifestations (peripheral neuritis, Guillain-Barre syndrome) in 11.1% of the cases, endocrine manifestations (impaired glucose metabolism, and hypothyroidism) in 19.4%, hematological (thrombocytopenia, hemolytic anemia, aplastic anemia) and cardiovascular manifestations. **Conclusions**: In our group of patients the extrahepatic manifestations often complicated the course of chronic HBV infection with a wide range clinical manifestations involving many organs or systems (skin, joints, nervous, renal, cardiovascular and hematologic systems). **Keywords:** PANARTERIS NODOSA, ESSENTIAL MIXED CRYOGLOBULINEMIA, ACANTHOSIS NIGRANS.

The current importance of acute hepatitis B virus (HBV) infection is due to its widespread around the world, high potential for chronicity and possible progression to liver cirrhosis or hepatocellular carcinoma. Hence the interest of researchers to supplement the data accumulated so far regarding the pathogenesis, clinical and laboratory aspects of HBV infection. Progression to chronic forms is accompanied by a persistent production of immune complexes (which fix and activate the complement) causing extra hepatic lesions. Autoimmune phenomena, with the presence of circulating nonspecific auto antibodies (antinuclear, anti-mitochondrial and anti-albumin) have been

also reported. There are numerous extrahepatic syndromes associated with HBV infection: vascular (vasculitis, panarteritis nodosa), renal cutaneous (papular dermatitis), essential mixed cryoglobulinemia and neurological phenomena (3.4).

MATERIAL AND METHODS

The cases of chronic HBV infection admitted to the Iasi "St. Paraschieva" Infectious Diseases in Iasi in the interval 2012-2014 were retrospectively studied. The 180 patients included in the study were diagnosed by physical examination, liver function, serological, virological and histological tests. Our aim was to determine the prevalence and course of extrahepatic manifestations during the disease in view of adjusting the regimens, on the one hand for treating these complications and, on the other hand, for rethinking the strategy for monitoring and treating the patients with chronic HBV infection (as some therapeutic interventions to manage these complications can negatively influence the course of the underlying disease, as it is the case with panarteritis nodosa (PAN).

RESULTS

The 180 patients included in the study accounted for 8.7% of all chronic hepatitis cases admitted during the study period. The mean age of the study patients was 41 years (range 18-66 years), most patients being male (65%) and living in urban areas (70%). The extra hepatic manifestations encountered during the course of chronic hepatitis C are listed in table I.

TABLE I
Extrahepatic manifestations associated with chronic hepatitis B

System	Manifestations	No.	%
Locomotor	Arthralgia	34	18.9
	Arthritis	3	1.7

During the course of chronic HBV infection cutaneous manifestations were present in 62% of patients. *Rash* was encountered in about 25% of patients. *Gianotti-Crosti* syndrome or *"papular acrodermatitis of childhood"*, which is a self-limiting papular or papulovesicular rash, was present in the acute phase of infection in 6 cases, especially among women (15% cases) and young adults, being located in most cases on the distal portion of the limbs and accompanied by pruritus. The recovery occurred spontaneously after 25-45 days and the associated manifestations included fever, diarrhea, and lymphadenopathy.

Cryoglobulinemia was present in 38 (21.1%) cases and *Henoch-Schonlein* purpura in 22 (12.22%) cases. *Essential mixed cryoglobulinemia* is described in association with the HBsAg carrier status; in our study group it manifested by: purpura (14 cases), Raynaud syndrome - 46 (25.6%) cases and arthralgia - 34 (18.9%) cases, triggered by exposure to cold. Fatigue was present in all cases, and renal involvement was found in 29 (16%) cases, manifested by glomerulonephritis (membranoproliferative type with marked monocyte infiltration). Three of the patients also had chronic kidney failure.

Panarteritis nodosa (PAN) is a rare event, but severe in chronic hepatitis B; in our study its prevalence was of 5% (1, 2). Cutaneous PAN was found in 9 (5%) cases, with the following manifestation*: livedo reticularis* and *painful subcutaneous nodules*, ulcerated nodules and distal gangrene manifested by fever, polyarthralgia, myalgia , nettle rash, hypertension, neuritis, soft tissue nodular lesions, *livedo reticularis*, and in severe forms: cutaneous ulcers, distal gangrene acute colecystitis, vascular occlusions. Other encountered cutaneous extrahepatic manifestations were: *nonspecific rash*: maculopapular - 45 (25%) cases, *livedo reticularis* - 3(1.7%) cases, erythema nodosum - 46 (25.6%) cases, stellar angioma -14 (7.77%) cases and *palmar erythrosis* - 6 (3.33%) cases; *acanthosis nigrans* was present in 2(1.1%) cases. Late cutaneous porphyria: dysmetabolic condition associated with uroporphyrin-decarboxylase deficiency has been associated with the presence of anti-HBc antibodies in blood, being reported in one patient. The manifestations at the level of the locomotor system were represented by *arthralgia*-34(18, 9%) cases and *arthritis*-3(1,7%) cases and were clinically characterized by polyarthralgias and arthrites accompanied by joint swelling, the joint involvement being symmetrical, generalized, and affecting especially the small joints of the hand and foot.

The renal extrahepatic manifestations consisted in *glomerulonephritis*, seen in 5 (2.77%) cases, *nephrotic syndrome*, proteinuria and hematuria. Immune complex deposits in patients with viral hepatitis have been detected in the kidneys in the absence of kidney disease and the most common form of glomerulonephritis in chronic hepatitis B was the nephrotic syndrome. *Proteinuria* and *hematuria* were reported in 2 (1, 1%) cases and were accompanied by fever. Neurological manifestations related to the action of HBV or to the induced immune response were present in 20 (11.1%) cases. These were classified as early and late, occurring several weeks after the onset, and included: *peripheral neuritis* (which occurred 4-21 days after the onset) in 6(3.3%) cases; *polyneurites* - 11 (6.1%) cases, *Guillain-Barre syndrome* - 8 (4.4%) cases and *extrapyramidal syndromes* -2 (1.1%) cases. The endocrine events were represented by *disorders of glucose metabolism* -35(9.4%) cases and

hypothyroidism -15(8,3%)cases. The recorded hematologic manifestations in order of their frequency were: *thrombocytopenia* -95(52.7%) cases, *hemolytic anemia* - 34 (18.8%) cases, and phenomena *of aplastic anemia* in 2 (1,1%) cases. Cardiovascular manifestations during chronic hepatitis B were seen in 43 (23.8%) cases, being represented by: *myocarditis*- 1 (0.6%) cases, phenomena of *hypotension* in 28(15.6%) cases, *bradycardia* -5 (2.2%) cases and *tachycardia* in 8 (4.4%) cases. Also recorded were digestive manifestations in 49 cases: *gastritis* 18 (24.4%) cases and *biliary dyskinesia* in 31(17.2%) cases.

DISCUSSION

The pathogenesis of extrahepatic manifestations in chronic hepatitis B is generally immune mediated. Panarteritis nodosa (PAN) is rare, with a prevalence of 1-5%, but a very severe complication of chronic HBV affecting the small and medium-sized vessels. It is more common among patients in North America and Europe but rare in Asians. In our study its prevalence was of 5%, thus concords the values reported in the literature. The incidence of HBV infection in patients with PAN ranges from 30% to 70%. In the US and Europe, where HBV infection is late the association with PAN is prevalent compared to Asia where HBV transmission is predominantly perinatal and the association of PAN has not been reported. Guillevin et al. (7) show that the clinical manifestations of HBV-associated PAN were similar to those of typical PAN except for: gastrointestinal complications (perforation and bleeding, present in 46.3% of cases), malignant hypertension (29.6% cases), renal infarction and orhi-epididymitis (26%). Untreated, the prognosis of HBV-associated PAN is poor, with 30-50% mortality, consequence of vasculitis (3, 4). In glomerulonephritis, the HBsAg-anti-HBs circulating immune complexes were identified in the glomerular basement membrane (5). All three major antigens of HBV (HBsAg, HBeAg and HBcAg) were located in the glomerular capillary wall or mesangium. Deposits of immune complexes in patients with viral hepatitis were detected in the kidney even in the absence of kidney disease. The most common form of glomerulonephritis in chronic hepatitis B was the nephrotic syndrome. Healing is frequently associated with HBsAg seroconversion and only a small proportion of patients' progresses to kidney failure (4).

"Arthritis-dermatitis" syndrome is common among patients with chronic hepatitis B, being present in about 1/3 of patients (6, 7). Joint and skin manifestations are varied and remit spontaneously (8). The association between HBV and essential mixed cryoglobulinemia remains controversial. There are 3 types of cryoglobulins; Type II (monoclonal IgM and polyclonal IgG) and type III (polyclonal IgM and monoclonal IgG) cryoglobulins are classified as essential and are found in patients with chronic HBV infection. The prevalence of cryoglobulinemia ranges from 0% to 15% (9, 10). Purpura and arthralgies are the most frequent manifestations. Cryoglobulinemia is frequently associated with Raynaud's phenomenon, arthritis and Sicca syndrome, which can cause renal, neurological and vascular complications (1, and 10).

CONCLUSIONS

In our study group the extrahepatic manifestations have often complicated the course of chronic hepatitis B taking a wide range of clinical forms and involving many organs or systems (skin, joints, nervous, renal, cardiovascular, and hematologic systems). Their recognition may contribute to

early diagnosis of chronic HBV infection and effective treatment. Although in the literature the incidence of chronic hepatitis B-associated PAN is of 1%-5%, in our study is was of 5%. The importance of diagnosing the extrahepatic manifestations is related to therapy, as corticotherapy can negatively influence the course of chronic HBV.

ARE THERE ANY PARTICULARITIES IN CROHN'S DISEASE IN NORTH-EASTERN ROMANIA? (Abstract): Crohn's disease is an inflammatory disease of the gastro-intestinal tract with an evolution marked by activity and remission periods. Lately, the incidence and evolution models of Crohn's disease significantly changed, an increasing number of patients presenting more severe forms. **The aim** of the study is to analyze Crohn's disease in its phenotypic classification and to establish correlation between the localization, the behavior and the activity of Crohn's disease. **Material and methods:** A transversal study on 53 patients with Crohn's disease was conducted. **Results:** from the 53 patients, 56.6% were males, 85% from the urban areas. Under the phenotype aspect, the colonic localization (49.1%) and the inflammatory behavior (52.8%) were predominant. More severe forms of activity were discovered to patients with ileal localization (57.1%) or with penetrant phenotype (33.3%). **Conclusions:** Male patients from urban areas were predominant. The most frequent forms are the colonic and ileocolonic forms. From a behavioral point of view, we observed an obvious predominance of the inflammatory phenotype. The moderate - severe activity was predominant for the ileal localization and the mild - moderate activity for the colonic and ileocolonic localization. A mild-moderate activity is present for the stenosing forms and a moderate -severe one for the penetrant forms. **Keywords:** CROHN'S DISEASE, PHENOTYPE, LOCALIZATION

Crohn's disease (CD) is a chronic inflammatory disease of the gastrointestinal tract of unknown etiology. Both genetic and environmental factors (i.e. smoking) have been incriminated in its pathogenesis (1, 2). Over the last two decades, Crohn's disease incidence model has significantly changed (3,4). A high number of patients have been shown to develop more severe forms of the disease (penetrating or stenosing) in time. Nonetheless, there are still relatively limited data regarding the natural history in population studies.

The classification of Crohn's disease based on phenotypic criteria plays an important role in patient management and could prove to be helpful in determining the patient's clinical course (5).

In 1998, at the International Congress of Gastroenterology in Vienna, a classification of CD was established by taking into account the following factors, as the main

phenotypic elements (6): age (under 40 and over 40 years old), localization of the lesions (L1 terminal ileum, L2 colonic, L3 ileocolonic and L4 upper gastrointestinal tract) and disease behavior (B1 non-stenosing, non-penetrating, B2 stenosing, B3 penetrating).

The reevaluation of the classification from Montreal in 2005 did not change the categories of the classification from Vienna, but it made changes in each of these categories (7). As regards the age of onset, the Montreal classification considers the early onset of the disease for patients aged fewer than 16 as a new category, while the patients aged between 17 and 40 and over 40 years old were placed within categories A2 and A3. This change reflects numerous studies that demonstrate the presence of specific serotypes or genotypes which are more common in patients with an early onset of Crohn's disease (6, 9, 10).

In terms of the localization of lesions, the main problem of the classification from Vienna was the separate classification of the lesions of the upper gastrointestinal tract. Once with the emergence of new methods of investigation (capsule endoscopy), the localizations from the upper gastrointestinal tract were observed to coexist with lesions located at the level of the bowel or colon, therefore, they were no longer excluded from the classification from Montreal. Changes were made in the new classification also as regards the phenotype of the disease based on the observation that the perianal manifestations are not associated only with the penetrating disease. Thus, the authors added a special category for the perianal manifestations that can be added to the other categories of the disease behavior. After establishing the diagnosis and the phenotype, it is essential to monitor the disease in terms of activity. The activity score of CD (CDAI) is the index most used to estimate the severity of CD, widely used in clinical trials for over 25 years. However, CDAI has certain limitations, due to the subjectivity of some parameters such as well-being or pain intensity (11).

Based on these data, our study aims to analyze patients with CD in terms of their phenotypic classification, as well as to establish associations between the localization and behavior of Crohn's disease and its activity.

MATERIAL AND METHODS

A cross-sectional study was conducted on 53 patients with an established diagnosis of CD in the period from October 2011 to April 2013.

A worksheet was compiled for each patient comprising personal data (name, age, sex, place of origin), family and personal history, symptoms and signs of the disease, clinical data established after objective clinical examination, complete biochemical profile.

All patients underwent total colonoscopy, and in cases of suspected small bowel lesion in Crohn's disease, additional tests were requested (capsule endoscopy, computed tomography, magnetic resonance imaging).

The severity of CD was classified according to the activity score of CD (CDAI).

RESULTS

The age of the patient with CD ranged between 19 to 67, with an average value of 39.23 ± 12.64 years old. The average value was slightly higher in females (40.09 ± 9.89 years old) than in males (38.57 ± 14.53 years). Thirty patients were male, representing 56.6% and 23 female (43.4%), resulting a sex ratio of 1.3 / 1. Most pa-

tients came from urban areas (85%).

The data analysis in patients with CD showed that the most common localizations of the disease were the colonic (49.1%) and the ileocolonic (34%). It should be noted that the CD was located in the upper gastrointestinal tract only in 2 patients representing 3.8%. The CD was located in the bowel in 13.2% of patients. From the point of view of the phenotype, there was a clear predominance of the inflammatory phenotype, being present in more than half of the patients (52.8%). The stenosing and penetrating phenotypes were relatively equally represented in a ratio of 24.5% and 22.6% respectively (tab. I).

The case studies on the patients with Crohn's disease showed that moderate-severe forms predominated in patients in which CD was located in L1 (57.1%) and mild-moderate forms in those in which CD was located in L2 and L3 (30.8% and 27.8% respectively), the results providing statistically significant percentage differences (p = 0.04) (tab. II).

TABLE I

Characteristics of the patients with CD

Parameter	*Number of patients*
Age	
A2	29 (54.8%)
A3	24 (45.2%)
Location	
L1	7 (13.2%)
L2	26 (49.1%)
L3	18 (34%)
L4	2 (3.8%)
Behavior	
B1	28 (52.8%)
B2	13 (24.5%)
B3	12 (22.6%)

TABLE II

The association of severity with the location of Crohn's disease

Location	*L1*		*L2*		*L3*		*L4*	
	n	*%*	*n*	*%*	*n*	*%*	*n*	*%*
Mild-moderate	2	28.6%	8	30.8%	5	27.8%		
Moderate-severe	4	57.1%	4	15.4%	2	11.1%	1	50.0%
Sever-fulminant			2	7.7%				
Remission	1	14.3%	12	46.2%	11	61.1%	1	50.0%

Significant differences emerged according to the severity of Crohn's disease on the phenotypes of the lesion (p=0.001): the patients in remission predominate regardless of phenotypes; on the other hand, in patients with phenotype B2, mildly-moderate forms predominate (38.5%), while in patients with B3 phenotype, moderately-severe forms predominate (33.3%) (tab. III)

TABLE III

The association of severity with the pattern of Crohn's disease

Severity	*B1*		*B2*		*B3*	
	n	*%*	*n*	*%*	*n*	*%*
Mild-moderate	7	25.0%	5	38.5%	3	25.0%
Moderate-severe	6	21.4%	1	7.7%	4	33.3%
Sever-fulminant	1	3.6%	1	7.7%		
Remission	14	50.0%	6	46.2%	5	41.7%

DISCUSSION

The specialized literature on the distribution of lesions in Crohn's disease is extremely varied. The IBSEN cohort study carried out in Norway on 200 patients showed that in 27% of the cases, the CD was located in the ileum, 45% of the patients had colitis-type CD, 26% ileocolitis-type CD and in 4% of cases the lesions were located in the upper tract (12).

The results were similar in another study in which the incidence of ileitis was of 15%, of isolated colitis of 42%, of ileocolitis of 37% and of the location at the level of the upper gastrointestinal tract was of 6% (13).

On the other hand, slightly contradictory data have been reported in the study carried out by Lewis. In this study, there is a clear predominance of the ileal form in 57% of cases, followed by Crohn's colitis in 27% of cases, ileocolitis in 19% of cases, and locations at the level of the upper tract in only 4% of the cases (14).

As regards the location of the lesions, the results of our study are similar to those reported in the specialized literature: ileal location in 13.2% of the cases, colonic in 49.1%, ileocolonic in 34% and lesions at the level of the gastrointestinal tract in 3.8% of the cases. However, there is a majority of approximately 49% of cases of colitis, a higher percentage than the one reported in the specialized literature, possibly also due to the subdiagnosis of localizations in the small intestine in the context in which colonoscopy is much more accessible than CT enterography or MR enterography investigations or capsule endoscopy exploration of the small intestine or due to regional peculiarities of the disease.

As regards the Montreal classification, there is controversy in the specialized literature in terms of phenotypes. Recent studies have shown that, over time, the phenotype of Crohn's disease can change, the patients with an inflammatory form at the onset being able to develop stenotic or fistulizing complications in the follow-up period of 5, 10 or 20 years (15).

The authors of the Norwegian IBSEN cohort study reported stenosing phenotype in 28% of the patients, fistulizing in 12% and inflammatory in 61% of the patients. After a 5-year follow-up period, the percentages changed significantly, showing an increase in the number of fistulizing and stenosing forms to the detriment of the inflammatory ones. After 5 years of follow-up, 33% of the patients had stenosing phenotype, the fistulizing forms increased to 21%, while only 47% of patients had non-stenosing, non-fistulizing phenotype (12).

In the EC-IBD study, a much higher rate of the inflammatory phenotype, of 78%, was identified in patients with Crohn's disease, while the stenosing and fistulizing forms were diagnosed in much fewer patients, namely 16% and 8% respectively (13).

In a cohort study performed in France on 1199 patients with Crohn's disease, monitored over a period of 8.6 ± 7.9 years, 60% of the patients developed stenosis or fistula. Of these, 13% developed stenosis, 27% developed perianal fistula and 20% intestinal fistulas. The stenosing lesions were associated with ileal and jejunal forms, and the fistulizing ones were associated with colonic localizations (16).

This discrepancy of data from one study to another is also explained by the lack of uniformity in estimating phenotypes in many centers. In some patients, the diagno-

sis of stenosis or fistula was established intraoperatively, without being identified prior to the surgical procedure by means of imaging methods.

In our study, the phenotype analysis highlights a majority of 52.8% of the non-stenosing, non-fistulizing phenotype, the stenosing and fistulizing forms being found in 24.5% and 22.6% of cases. Even though the inflammatory form predominates, there are an increased number of cases of complicated forms, possibly also due to the fact that the study was conducted in a tertiary care center providing treatment for more complex medical cases.

In terms of the association with the disease activity, the moderately severe lesions predominate in patients with ileal localization of the disease and the mildly-moderate forms predominate in patients with colonic and ileocolonic localization. We consider the higher degree of severity of the disease in intestinal forms to be explicable, as these are the localizations most frequently associated with weight loss, palpable mass, abdominal pain, symptoms that fall into the calculation of the CDAI severity score.

Our study shows that the mild-moderate forms predominate in the stenosing phenotype, while the moderately severe forms predominate in patients with penetrating phenotype. We interpret the association between the stenosing phenotype and the mild-moderate activity in the context of systemic manifestations that are less expressed than in the other phenotypes, the symptomatology being insidious until complications such as intestinal obstruction occur. On the other hand, the penetrating phenotype is more frequently accompanied by complications such as fistulas and abscesses having a more visible mark on the classes of symptoms that make up the CDAI score.

CONCLUSIONS

In our study, male patients from the urban areas predominated. The most common localizations involved the colon (colonic and ileocolonic forms). In terms of phenotype, there is a clear predominance of the inflammatory phenotype, which was present in more than half of the patients. Nonetheless, the more complicated forms of the disease (stenosing and penetrating) were identified in an increasing number of patients, largely due to the fact that the study was performed in a referral center. The moderate - severe activity was predominant for the ileal localization and the mild - moderate activity was predominant for the colonic and ileocolonic localization .The stenosing forms were most frequently characterized by mild-moderate activity, while the penetrating forms were most frequently characterized by moderately severe activity.

ADVERSE REACTIONS OF BIOLOGICAL THERAPY FOR PSORIASIS (Abstract): **Aim:** To detect in patients with psoriasis the adverse effects during TNF-α inhibitor therapy. **Material and methods:** Fifty-seven patients with psoriasis, aged between 12 and 75 years were analyzed. They were treated with different TNF-α antagonists, the maximum treatment duration being 59 months. All patients were followed monthly after the initiation of therapy by clinical checkup, then every 3 months during the first 6 months of treatment by laboratory screening, and then every 6 month. Chest x-ray and tuberculin intradermal skin test were performed annually or as needed. All symptoms reported by patients were recorded, the treating doctor deciding the need for additional investigations or specialist consult. **Results:** Of the total of 57 patients with psoriasis on biological therapy, 9 patients developed diseases requiring temporary or permanent discontinuation of therapy. The recorded adverse reactions were: infectious (pulmonary tuberculosis, pulmonary empyema), oncologic (rectal cancer, renal cancer), dermatologic (vesiculobullous erythema multiforme major, nodular hypodermtis, secondary erythroderma, and hives) disorders. **Conclusions:** Despite its adverse reactions, biological therapy is safe and is a necessary tool in the treatment of moderate and severe forms of psoriasis unresponsive to other treatments. **Keywords:** PSORIASIS, BIOLOGICAL THERAPY, ANTI-TNF-α.

Psoriasis is a chronic inflammatory disease, affecting the growth and differentiation of the epidermis, with polygenic predisposition and various trigger factors (infections, drugs, physical or emotional trauma, stress) (1, 2). Its prevalence ranges from 0.1 to 11.8% in Europe and the United States, with an average incidence of 2-2.5% and equal gender distribution (3, 4).

Biological therapy in dermatology represented an important step in treating chronic conditions with significant impact on patient quality of life. For the treatment of psoriasis there are already a number of molecules with favorable results, some approved for years, others new, of which we mention the anti-CD11a agents (efalizumab), anti-TNF-alpha agents (etanercept, adalimumab, infliximab), and IL-12/IL-23 antagonists (ustekinumab). The mechanism of action of these agents consists in specific blocking of certain steps in the cascade of molecular events involved in the pathogenesis of this complex disease. Being a

last generation therapy, trials to assess its side effects and compare the effects of these molecules are in progress, and their long-term safety is continuously assessed (3, 4).

MATERIAL AND METHODS

The study group included 57 patients with psoriasis, aged 12 to 75 years, most of them from rural areas (35 patient = 61.4%). They received different TNF alpha antagonists, the maximum treatment duration being 59 months. During treatment, 9 (15.78%) of the 57 patients developed adverse reactions. All patients were followed up monthly after the initiation of therapy by clinical checkup, then every 3 months during the first 6 months of treatment by laboratory screening (blood count, ESR, creatinine, SGOT, SGPT, urine test), and then every 6 months. Chest x-ray and tuberculin intradermal skin test (IDR) were performed annually or as needed, depending on patient complaints and findings of pneumology consultation. All symptoms reported by patients were recorded, the treating doctor deciding the need for additional investigations or specialist consults. The correct administration was rigorously followed no matter of the molecule recommended for treatment.

RESULTS

Of the total of 57 psoriasis patients on biological treatment, 9 (15.78%) patients developed diseases requiring temporary or permanent discontinuation of therapy. The recorded adverse reactions were: infectious (tuberculosis, pulmonary empyema), oncologic (cancer, rectal cancer, renal cancer), dermatologic (vesiculobullous *erythema multiforme* major, nodular hypodermitis, secondary erythroderma, hives).

Of these, 4 presented lung infections: 3 (5.26%) patients developed pulmonary tuberculosis, 1 (1.75%) patient on treatment with infliximab and another (1.75%) patient on adalimumab. Another (1.75%) patient was diagnosed with pulmonary tuberculosis after the switch from infliximab to adalimumab due to lack of efficiency. The fourth patient developed pulmonary empyema after therapy with etanercept (1.75%). The shortest interval between the initiation of biologic therapy and the occurrence of infectious complications was 3 months for infliximab, 5 months for etanercept, and the longest, 59 months, for adalimumab.

In the patient in whom the pathologically confirmed left secondary infiltrative nodular pulmonary occurred short time after the initiating biologic therapy with infliximab, i.e. three months, we suspect a poor screening, resulting in the reactivation of a latent form of tuberculosis. Before the lung disease was detected, treatment with infliximab resulted in a moderate decrease in PASI score (Psoriasis Area Severity Index) from 39.3 to 30.8. After 38 months, following triple TB treatment (isoniazid, rifampicin and pyrazinamide) and confirmation of clinical and bacteriological cure, a switch to adalimumab was initiated. The patient is still on adalimumab treatment, totaling 28 months.

The patient who after 22 months of infliximab treatment was switched to adalimumab due to lack of efficiency (initial PASI = 55.2, PASI at 22 months = 29.4, < 50% of baseline PASI) developed pulmonary tuberculosis 10 months after switching. Incriminated were the socioeconomic status, conditions, underweight, diet low in vitamins and nutrients, and poor rural are he lives in.

The patient on systemic treatment with adalimumab for 57 months, with an obviously favorable course of skin symptoms (PASI score at onset = 26.8, then it gradually decreased to 6.1 at 3 months, 1.2 at 6 months, reaching 0 after 12 months of treatment) was diagnosed with pulmonary tuberculosis, pathologically confirmed by bronchoscope biopsy. The onset form of skin disease was psoriasis vulgaris, but subsequently after applying a topical irritant (Swedish bitters) it turned into a generalized pustular psoriasis treated with long-term systemic corticosteroids. Disease-induced immunosuppression and exacerbated by prolonged systemic corticosteroids probably favored the occurrence of active tuberculosis.

In the study group, malignancies were recorded in 2 (3.50%) patients none of them with a family history of cancer. One of these 2 patients with psoriasis was treated with infliximab for 28 months and due to the lack of response reflected in PASI score = 18.2 (PASI score <50% of baseline PASI = 24.5) he was switched to adalimumab. The course of psoriasis lesions was favorable (PASI at 3 months = 12.4, at 6 months =1.2, and at 12 months =0). But, after 11 months of treatment with adalimumab the presence of a left renal tumor stage cT1bN0M0 was detected, and consequently adalimumab was discontinued. Left radical nephrectomy was performed and pathology findings confirmed the diagnosis.

The second patient was treated with adalimumab for 40 months, with a favorable course of skin lesions and psoriasis-related joint disease (PASI score decreased gradually from 24.2 at baseline to PASI = 8.1 at 3 months, PASI = 0.4 at 6 months, and PASI = 0), until because of fresh blood rectorrhages he was referred to the gastroenterology unit. Colonoscopy revealed a vegetant, friable tumor mass, 10-12 cm from the anus, for which the pathology diagnosis was of infiltrating, moderately differentiated adenocarcinoma. A Hartmann operation with mesorectal excision was performed, the final diagnosis being ampullary mid-rectal cancer.

Adverse dermatological reactions were reported in 4 (7.01%) patients. After 5 months of etanercept, 1 (1.75%) patient presented pleural empyema, so the treatment was discontinued. One month after the last etanercept administration the same patient developed nodular hypodermitis, diagnosis confirmed by pathological examination of skin biopsies. Immediately after this event, the patient received treatment with sulfasalazine for 1 year and for 54 months she is on therapy with adalimumab. After 24 months, due to the severity of joint lesions methotrexate 7.5 mg/week was added at the recommendation of a rheumatologist, with a slowly favorable course, without complete remission of skin lesions, in the context of an unfavorable family climate (husband with lower limb amputation, daughter's death). Initial PASI was 51.2, and decreased gradually during the 54 months to PASI = 4.3.

Another (1.75%) patient developed severe vesiculobullous *erythema multiforme* after 4 weeks of infliximab administration, namely after 2 injections of infliximab, which responded well to short-term average-dose systemic corticosteroids. After the remission of allergy episode the patient resumed the biologic treatment regimen for the treatment of psoriasis with a favorable outcome. After 4 months the patient decided to discontinue the treatment in view of conceiving a child, but the occurrence of

psoriasis lesions within the 16-week free interval required the introduction of a new biological treatment, namely adalimumab, followed for 59 months with a favorable course of psoriasis.

The other two (3.50%) patients, one on etanercept and the other one on infliximab, developed secondary erythroderma after 19 and 30 months, respectively. On therapy, PASI score had an undulating course in both cases, starting from PASI = 10.8 and PASI = 26.2, respectively, with a tendency to decrease and then increase due to lesion accentuation and extension. Additionally, the patient receiving infliximab also presented at the next infusion, after another two months, an episode of acute urticaria, resolved by the administration of antihistamines. In both cases, treatment was discontinued due to its lack of efficiency, PASI score reaching 26.2 and 52.6, respectively at last reassessment.

Three of the patients experiencing adverse reactions to the administered biologic therapies, namely the patient with pulmonary tuberculosis occurred after 3 months of infliximab, the patient with ampullary mid-rectal cancer and the patient with pleural empyema and nodular hypodermitis were also diagnosed with psoriatic arthropathy. These patients have an additional depression of their immune status due to the aggressiveness of the arthro-pathy disease itself.

In our patients the degree of immunosuppression differed, being higher in those who received treatment with methotrexate and general corticotherapy (patient with pulmonary tuberculosis after 57 months of adalimumab treatment), followed by therapy with methotrexate (therapy administered prior to biologic therapy in 6 of the 9 patients), less affected being the only patient on PUVA (Psoralen and ultraviolet A light) therapy prior to biologic therapy (who developed *erythema multiforme* after 2 infliximab infusions, subsequently switched to adalimumab).

DISCUSSION

Before the introduction of mandatory screening for active pulmonary tuberculosis, its rate was high during biologic therapies, accounting for 19/100,000 patients a year (5). Later, when all patients on biologic therapy were screened for tuberculosis, between 2002 and 2006 its incidence has decreased to 7 (5). In case of 100% compliance with the screening protocol tuberculosis rate decreased to 1.8 per 100,000 patients a year but increased to 13 if compliance was below 100% (5).

In our study group the screening for active pulmonary tuberculosis was performed in 100%. Of all 57 patients on biologic therapy, 25 underwent isoniazid chemoprophylaxis as recommended by the pulmonologist. None of the 3 patients who developed pulmonary tuberculosis required prophylactic medication according to the screening performed prior to the initiation of biologic therapy.

Most cases of tuberculosis on adalimumab treatment occurred during the first 8 months of treatment (6). In our study, 1 of the 57 patients developed tuberculosis after 57 months of treatment with adalimumab.

The literature (7) suggests an increased incidence of neoplasms among patients with psoriasis without biologic treatment, compared with the general population. Patients with psoriasis are at a 76% higher risk for developing skin cancer and a 82% higher risk for developing lymphoma compared to subjects in the control group

(without psoriasis), with a statistically significant p value <0.001.

In patients with rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis and Crohn's disease, malignancies, except lymphoma and non-melanoma skin cancer, have occurred at a rate of 0.6 per 100 patient-years versus a rate of 0.4 per 100 patient-years for placebo-treated patients. The mean treatment duration was 5.7 months for adalimumab and 5.5 months in the control group (7). In clinical trials (7), the most common cancers other than lymphoma and non-melanoma skin cancer were breast, colon, prostate, and lung cancers and melanoma. The incidence rate of these cancers is similar to that in general population.

Dermatological adverse reactions reported in the literature (6) were: cellulitis, erysipelas, cutaneous vasculitis, *erythema multiforme*, Stevens-Johnson syndrome, alopecia, worsening of psoriasis or occurrence of other forms of psoriasis in the same patient.

As to etanercept, new cases or reactivation of tuberculosis have been reported, including patients on treatment for latent or active tuberculosis. Studies suggest that the risk of latent tuberculosis reactivation is lower compared with therapy with TNF-alpha blocking monoclonal antibodies (8, 9). Tuberculosis was reported in approximately 0.01% of patients in trials globally. The risk of developing severe infections is higher in those on therapy associated with immunosuppressive drugs such as methotrexate, and patients older than 65 years. As to malignancies, it was found that in patients on treatment with etanercept the risk of developing lymphoma is about 3 times higher than in general population. Cases of acute or chronic leukemia (0.06 cases per 100 patient-years) *versus* 0 in the control group have been reported. Duration of controlled treatment ranged from 3 to 48 months (10). Sixty-seven malignancies other than lymphoma have been reported, among which the most common are colon, breast, lung, and prostate cancers. In patients with psoriasis, 22 of 1261 (1.74%) patients were diagnosed with cancer. Of these, 9 were non-cutaneous solid tumors, 12 non-melanoma tumors (8 basal cells, 5 squamous cells) and 1 patient had Hodgkin lymphoma. Among placebo-treated patients only one developed two squamous cell cancers (10). Of the cutaneous adverse reactions we mention: *lupus erythematosus*, cutaneous vasculitis (including leukocytoclastic vasculitis), *erythema multiforme*, Stevens-Johnson syndrome, Lyell syndrome, subcutaneous nodules, worsening or occurrence of a new type of psoriasis in the same patient (10).

As to infliximab, during clinical trials tuberculosis was reported in 14 patients, of whom four died. Most tuberculosis cases were diagnosed during the first 2 months after the initiation of infliximab therapy (11). In our study group, one patient developed tuberculosis 3 months after the initiation of therapy. Infiximab treatment was discontinued and after 3 years therapy with adalimumab was initiated, the patient still being on this treatment, with a favorable course for 26 months.

Cases of lymphoma, skin, breast, and colorectal cancer, leukemia, Sezary syndrome, Merkel cell carcinoma, hepatosplenic T-cell lymphoma (most often in patients treated with infliximab - 20 compared with one in patients on etanercept, and 2 on adalimumab) have been reported. The risk of developing lymphoma is 3 times higher in those treated with inflixi-

mab compared to general population (12). The following cutaneous side effects have been reported: rash, which is the most common, followed in frequency of pruritus, cellulitis, ulceration, interstitial granulomatous dermatitis, furunculosis, psoriasiform rash, cutaneous vasculitis, erysipelas, atopic dermatitis, necrotizing fasciitis, bullous skin lesions, *tinea corporis*, *varicelliform exanthema*, palmoplantar pustulosis, atypical cutaneous leishmaniasis, *alopecia areata*, *herpes labialis*, cutaneous lymphomas, *erythema multiforme*, seen in patients with rheumatoid arthritis or Crohn's disease. In the interval August 1998 - August 2006, FDA (13) reported 21 severe skin reactions in patients treated with infliximab, of which 15 patients had *erythema multiforme*, 5 Stevens - Johnson syndrome and one case toxic epidermal necrolysis. The mean time to the occurrence of adverse reactions was 28 days after the first infusion, in this case exactly 4 weeks.

Studies comparing the effectiveness, safety and rate of side effects of these three molecules are useful. For example, Sallit et al. (8) in a recent retrospective study compared the infection rate in the same patients before and during treatment with TNF-alpha blockers. The infection rate after biologic treatment initiation was 34.5%, compared to 6.7% before treatment. Etanercept, adalimumab and infliximab were compared. The fewest infectious events were reported in patients on adalimumab (15.3% of patients), followed by etanercept (34.5%) and infliximab with the highest rate of infection (50.5 %). Instead, the rate of serious infections was lowest with etanercept (4%) (8). Other studies (9, 10) have also shown that the risk of developing certain infections is lower when using etanercept.

CONCLUSIONS

Despite the adverse reactions reported in this study, biologic therapy is safe and is a necessary tool in the treatment of moderate and severe psoriasis that do not respond to other therapies. Adverse reactions are usually very rare, but they must be quickly diagnosed and properly monitored. Systematic international reporting on adverse reactions to biologic therapy helps creating a clear image on the safety profile useful to the practitioner.

COMPARISON OF THE EFFECTIVENESS AND ANTIBIOTIC COST AMONG CEFTRIAXONE, ERTAPENEM, AND LEVOFLOXACIN IN TREATMENT OF COMMUNITY-ACQUIRED COMPLICATED URINARY TRACT INFECTIONS

Most of urinary tract infections (UTIs) are uncomplicated for healthy young women that are easily managed with short-term antimicrobial therapy. Complicated UTIs (cUTIs) may occur in both sexes at all age groups and are frequently associated with anatomical or functional urinary tract deficiencies. This research has compared the treatment of urinary tract infections with ceftriaxone, ertapenem and levofloxacin. At the same time, in this study, it was analyzed the quality-price ratio of the three antibiotics. The primary outcome was the time to defervescence after admission and the secondary outcome was duration of hospital stay. The antibiotic cost was calculated as the sum of all antibiotic usage during hospital course. The study compared the clinical characteristics and antibiotic costs in patients with cUTIs receiving three different antibiotics. Compared to patients in the other two groups, ertapenem group had shorter time to defervescence since admission and shorter hospitalization stay. The antibiotic cost was significant lower in ceftriaxone group. This study is subject to several limitations regularly found in retrospective studies. A well-conducted prospective study may be necessary in the future to elucidate the differences in treating cUTIs among the three agents. In conclusion ETP, CRO, and LVX in the treatment of cUTIs had good clinical response. (Lin H-A, Yang Y-S, Wang J-X et al. Comparison of the effectiveness and antibiotic cost among ceftriaxone, ertapenem, and levofloxacin in treatment of community-acquired complicated urinary tract infections. *J Microbiol Immunol Infect,* 2015.

INCIDENCE OF PRIMARY CARDIOVASCULAR RISK FACTORS IN PATIENTS WITH ERECTILE DYSFUNCTION (Abstract): **Aim:** Identification of primary cardiovascular risk factors in patients with erectile dysfunction. **Material and methods:** The study included 308 apparently healthy men, with a mean age of 45±12.1 years. The Sexual Health Inventory for Men (SHIM) questionnaire was used to determine the following indices: BMI, blood pressure, blood glucose, cholesterol, triglycerides, etc. **Results:** The total incidence of cardiovascular risk factors was 56%: 45% in men aged up to 40 years (group I) and 74% in those over 40 years (group II). High blood pressure was found in 9% of the men in group I and 55% in those in group II ($p < 0.05$). Blood glucose levels were recorded in 5% of group I patients 24% in group II patients. Sixty-six percent of the men over 40 years were overweight compared with 16% of men under age 40. Dyslipidemia was present in 65% of group I versus 19% in group II. **Conclusions:** Our study shows that especially in men over 40 years of age erectile dysfunction is a vascular endothelial condition clearly associated with cardiovascular risk factors; the direct association between the severity of erectile dysfunction and increased levels of cardiovascular risk factors reflects their importance in the occurrence and course of the disease, which should be taken into account when diagnosing an erectile dysfunction and selecting the therapeutic approach. **Keywords:** ERECTILE DYSFUNCTION, CARDIOVASCULAR RISK, INCIDENCE.

Erectile dysfunction (ED) is characterized by the inability of a man to achieve and maintain erection sufficient to permit satisfactory sexual intercourse. The worldwide incidence of erectile dysfunction ranges from 19% to 57% and depends on the socioeconomic conditions (2). Linear correlations between ED and cardiovascular diseases with the highest death rate (1) have been demonstrated since the MMAS and Colonge studies conducted in 1994 and 1998. According to the MMAS study, 39% of men treated for a cardiovascular disease have indicated the complete absence of erection (3). In the Colonge study, the prevalence of erectile dysfunction in hypertensive men was 36%, compared with 19% of the control group (4). The risk factors for cardiovascular disease are shared with ED, namely age, atherosclerosis, hypercholesterolemia, dyslipidemia, obesity, hypodynamia, etc.

It is worth mentioning that over 35% of hypertensive men and 66% of men with cardiovascular disease for at least 5 years have ED (5, 6).

ED is largely a consequence of other diseases that can serve as an early marker of cardiovascular risk and an independent prognostic predictor of cardiovascular events in middle-aged and advanced-age men. ED and cardiovascular disease are rarely diagnosed concomitantly, with erectile manifestations occurring 2-3 years earlier. Because penile arteries are smaller in diameter than coronary arteries, atherosclerosis, at a similar degree of endothelial dysfunction, causes a significantly greater and earlier reduction in blood flow in the erectile tissues supplied by the affected vessels.

Currently, it is not known, and it is not supposed that primarily detected ED could be the consequence of other diseases, cardiovascular diseases included, the causes of this disease being often related to age, prostate diseases or some psychological causes.

The presented data demonstrate that the penile vascular bed is a sensitive indicator of systemic vascular diseases (7, 8) which requires the early detection of cardiovascular risk factors that would contribute to the correct diagnosis and initiation of the appropriate treatment.

MATERIAL AND METHODS

This is a prospective study that was conducted between 2010 and 2016 and included 308 patients who sought help for ED in the absence of other previously diagnosed and/or treated conditions. The age of patients ranged from 21 to 73 years, mean age 45 ± 12.1 years. The patients were divided into two groups according to age: ≤ 40 years, 152 patients (Group I) and >40 years, 156 patients (Group II).

To make the diagnosis and determine the degree of ED, we used the SHIM questionnaire. The attitude towards physical activity and smoking was studied. Physical and instrumental examination included: determination of body mass index (BMI), pulse rate and blood pressure. Also determined were: total cholesterol and LDL and HDL fractions, triglycerides and basal glucose level.

The study results are presented in absolute and relative values. For statistical processing, the *Epi Info*^{TM} version 7 (Centers for Disease Control and Prevention, Atlanta, GA, USA) was used.

RESULTS

The presence and degree of ED., Following the analysis of SHIM questionnaires a severe degree of erectile dysfunction was present in 55 patients (18%), including 16 (11%) patients in group I and 39 patients (25%) in group II (tab. I).

TABLE I

Degree of erectile dysfunction severity by study groups (n = 308 patients)

Degree of ED	IIFE5	Group I No %	Group II No %	Total No %
Severe	6.3±2.5	16 (11)	39 (25)	55 (18)
Moderate	13.2±1.8	59 (39)	79 (51)	138 (45)
Mild	17.8±1.9	77 (50)	38 (24)	115 (37)
Total		152 (100%)	156 (100%)	308 (100%)

A tendency for ED to worsen was found with aging, when most patients have moderate and severe forms of ED.

Cardiovascular diseases, arterial hypertension and ED share the same risk factors, namely hypodynamia, obesity, dyslipidemia, hyperglycemia, among others.

Of the 308 enrolled men, only 31% practice daily or regular sports and 29% have a sedentary activity. In people over age 40, sedentary activity is preferred by every other person, and among patients under 40, every fourth individual is physically inactive.

Only 88 patients (29%) said they were non-smokers, the remaining 71% smoked or had previously smoked. By age groups, the percentage of smokers was not significantly different. Differences were evident among non-smokers with ED. Among the young patients, the percentage of non-smokers was 55%, compared with 40% in patients over age 40.

Body Mass Index (BMI) assessment showed that in 180 (58%) patients BMI was less than 26 kg/m2, and 128 (42%) had excess body weight. By age groups there was a statistically significant difference in terms of excess body mass. In group I only 25 men (16%) had a high BMI, and only 3 (2%) were diagnosed with obesity, 127 (84%) being normal weight. Among the patients aged over 40, only 53 (34%) were normal weight, 60 (38%) were overweight and 43 (28%) were obese.

Blood pressure was determined in all patients. In individuals with high blood pressure, we performed repeated resting examinations at 10-minute intervals to exclude the influence of external factors. Repeated blood pressure measurements showed elevated levels in 100 patients (32%), including 14 (9%) group I and 86 (55%) group II patients.

Assessment of lipid profile showed that the level of cholesterol or its LDL fraction was elevated in 130 (42%) patients, with a statistically significant difference between study groups ($p < 0.05$). Thus, 101 (65%) patients belonged to group II and only 29 (19%) to group I. Triglyceride levels greater than 200mg/dl were recorded in 85 (28%) patients. Like previous situations, there was a significant age-related difference. Thus, in group I only 23 patients (15%) presented hypertriglyceridemia, compared to 62 (40%) in group II ($p < 0.05$).

The presented data demonstrate a significant dysregulation of lipid metabolism in over 65% of the patients older than 40 years with primarily detected ED.

TABLE II

Incidence of cardiovascular risk factors primarily detected in patients with erectile dysfunction by age groups

Risk factors	Group I, up to age 40 No %	Group II, over age 40 No %	Total No %
Absence of physical activity	86 (57)	123 (79)	209 (68)
Smoking	69 (45)	94 (60)	163 (53)
BMI >26 kg/m^2	25 (16)	103 (66)	128 (42)
Hypertension	14 (9)	86 (55)	100 (32)
Elevated cholesterol	29 (19)	101 (65)	130 (42)
Elevated triglycerides	23 (15)	62 (40)	85 (28)
Basal blood sugar>6.69	8 (5)	37 (24)	45 (15)

The increased incidence of obesity, dyslipidemia or changes basal blood glucose levels in elderly men is probably explained by the fact that the compensatory reserves of the body begin to deplete at that age.

Two or more cardiovascular risk factors were present in 116 (74%) patients aged over 40, as compared to 68% (45%) of the patients with erectile dysfunction aged up to 40.

Penile pharmaco-Doppler ultrasonography performed to determine blood circulation, systolic velocity, and degree of ED of vasculogenic origin in 95 patients (31%), representing 48 (32%) group I patients and 47 (30%) group II patients is shown in figure 1.

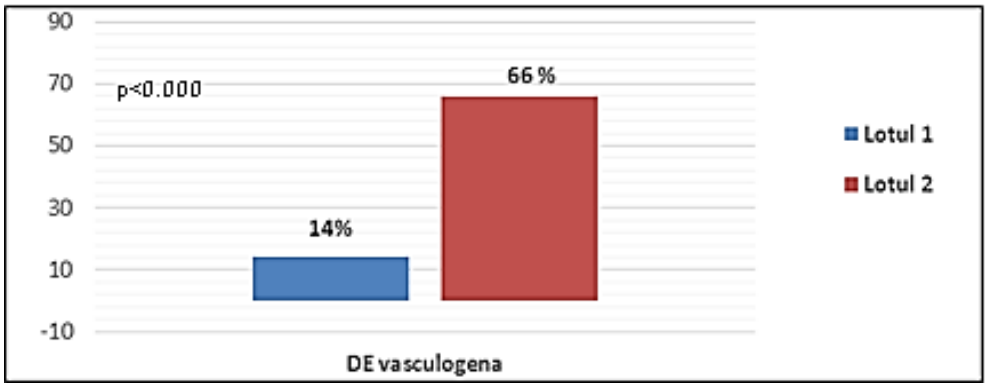

Fig. 1. Presence of erectile dysfunction of vascular origin in study group patients, according to penile pharmaco-Doppler ultrasonography (95 patients).

Determination of fasting basal blood glucose showed levels greater than 6.99 mmol/l in 45 (15%) patients, 8 (5%) in group I and 37 (24%) in group II, respectively. According to the criteria of the American Diabetes Association an increase in basal blood glucose after a single reading in the absence of metabolic decompensation criteria requires repeat testing on different days or a glucose tolerance test (9).

The results of penile Doppler ultrasound (fig. 1) showed a decreased blood flow with a decrease in systolic velocity, respectively the presence of a vasculogenic ED in 7 (14%) group I patients compared to 31 (66%) group II patients ($p < 0.0001$).

DISCUSSION

Cardiovascular diseases are still the leading cause of global mortality, stimulating the search for new directions in the early diagnosis of cardiovascular risk factors. Of major importance are the changes in vascularization at macro- and microcirculatory level induced by ischemia which are strongly dependent on intimal thickening of small intramyocardial arteries and increased coronary tone with diminished coronary blood flow and diminished dilatation of coronary arteries with decreased coronary reserve (10, 11).

ED is considered a derivative of cardiovascular diseases but equally as a possible vascular endothelial disease that is often the first manifestation of cardiovascular diseases. Data from scientific studies have shown that ED in patients over the age of 40 is in most cases associated with a cardiovascular disease not clinically manifest at the time of presentation, or with biochemi-

cal changes associated with increased cardiovascular risk. Montorsi's reference study showed that ED is present in 47% of patients with angina pectoris compared to 24% in healthy males. In patients with acute single-vessel coronary artery disease, the frequency of ED was of 22% and in case of double, or triple-vessel disease of 55%. The duration of ED may have a direct prognostic role for the subsequent risk of cardiovascular events (12).

The third Princeton Consensus Recommendations (13) have considered that ED can be a predictor of clinically nonmanifest cardiovascular diseases. Men who experience signs of ED require complex cardiovascular assessment, with the determination of exercise tolerance and risk of cardiovascular events. In case of a low risk, any treatment for ED may be initiated; the moderate risk involves some additional investigations, and the increased risk requires making a diagnosis and prior treatment of the possible cardiovascular diseases.

Our study aimed at assessing the cardiovascular risk factors in patients with ED who consider themselves healthy. In young patients the absence of cardiovascular risk factors was reported in more than 65%, ED having a rather psychological substrate, while in patients aged over 40 it was reported in only 26%, the organic substrate being the most common.

We have also identified the presence of some risk factors and have diagnosed some diseases in patients who considered themselves healthy. Thus, the incidence of hypertension was of 32%, and of 55% in men over 40 years of age. Fifteen percent of the study patients, 24% of patients aged over 40, respectively, had elevated blood glucose levels. Men with diabetes mellitus are at increased risk of developing ED, which usually occurs about 10 years earlier, compared to men without diabetes. Among the common risk factors, we noticed the high percentage of smokers, 53%. Smoking is one of the unanimously accepted risk factors for developing atherosclerosis and cardiovascular diseases even in the absence of hyperlipidemia and diabetes mellitus by inducing oxidative stress and contributing to the development of atherosclerotic plaques.

In this study, we found a relatively high incidence of obesity and hyperlipidemia, more common in the elderly. Sixty-six percent of elderly men had high BMI, compared with 16% of the younger men. The incidence of dyslipidemia in men older than 40 years with ED was 64%, compared to 19% in men aged up to 40. In some European studies, the incidence of dyslipidemia depending on age, gender and geographical region is 37.2% - 65% (14).

Often physical or sexual activity may be the cause of an acute cardiovascular event (15). Our study shows that patients with ED primarily detected when older than 40 years frequently associate a cardiovascular disease that should be considered when assessing such patients.

CONCLUSIONS

Our study demonstrates that especially in men over 40 years of age erectile dysfunction is a vascular endothelial disease with associated cardiovascular risk factors; the direct dependence between the degree of erectile dysfunction severity and the associated cardiovascular risk factors reflects their importance in the occurrence and course of this disease, and should be taken into account when making the diagnosis and selecting the therapeutic approach.

PROGNOSTIC FACTORS IN RESECTABLE PANCREATIC CANCER (Abstract): The pancreatic cancer is a disease with exponentially increased incidence, especially over the last decades, being the sixth or even fifth cause of death by cancer in most of the modern societies. Moreover, it is estimated that almost 95% of the patients with this disease are presenting to the doctor in the advanced and unresectable stages. Also, over the past few decades the development and advance of the surgical methods and techniques have improved only morbidity and hospital postoperative mortality, without significant impact on survival. In this way, in the present mini-review we want it to make a short description for some modern aspects regarding the factors implicated in pancreatic cancer survival. **Keywords:** PANCREATIC CANCER, SURVIVAL, MARKER, PROGNOSTIC FACTORS

Lately, the incidence of pancreatic neoplasm has increased steadily, with the pancreatic ductal adenocarcinoma being the most common malignant disease of the pancreas, with the origin in the ductal epithelium and with an incidence of 10-11 per 100,000 inhabitants in the Western countries and also being considered one of the most aggressive human tumors (1).

In addition, this is the fourth cause of death by cancer in North America, having approximately 31,000 new cases per year in Canada and in the United States and, unfortunately, about as many deaths each year, and the also the fifth cause of death by cancer in the Western hemisphere. Moreover, the fatality rate correlates with the age varies between 3.1 and 20.8 per 100 000 inhabitants with a corresponding peak for the patients between 60 and 80 years (2).

Also, surprisingly, despite the numerous studies about pancreas cancer, little is known about this issue. The resections for the cancer of pancreas have entered the therapeutic arsenal for 65 years, but despite the fact that hundreds of articles were written on this subject, there is no unanimity of opinion concerning the efficacy of resection. A number of authors have reported a 5 years survival rate of 30% or even 58%, being supportive of resection (3-5).

Moreover, most of the studies carried out have not been able to identify the significant risk factors for pancreatic cancer. Still, several risk factors were described as being involved: smoking, chronic pancrea-

titis, diabetes mellitus, previous gastrectomy and exposure to radiation or chemicals such as chlorinated hydrocarbon based solvents (6, 7).

Also, the prognosis of the patients with pancreatic cancer and an indication for curative intent resection is determined by lymphatic metastasis, vascular walls and nerve peripancreatic nerve plexuses invasion, and also by the progression of micrometastases in the neighboring tissues and organs.

Unfortunately, 95% of the patients arrive in the advanced, unresectable stages.

Thus, over the past few decades the development and improvement of surgical methods and techniques have improved only the hospital post operatory morbidity and mortality, however without having a significant impact on survival.

In this way, in specialized pancreatic surgery centers the mortality is less than 5%. Also, the long-term 5 years survival after R0 resection is reported in literature as being under 10% per series of screened patients, with no record of recurrence during this period. These results are at odds with other studies which reported the values of the actuarial 5 years survival between 20 to 40% of the resected patients. A possible explanation lies in the fact that the Kaplan-Meier statistical method for assessing the survival is excluding the patients deceased in hospital, as well as those who were lost in the surveillance. Therefore, other methods and criteria should be used to correctly assess the results of the resections, such as the actual survival.

Regarding the adjuvant treatment used for the prolongation of survival after oncologic resection, some studies have suggested the benefit for the application of adjuvant chemotherapy and radio chemotherapy for 6-10 months (even routine application to each patient was suggested!).

A neoadjuvant protocol for pancreatic cancer is reconsidered in recent years, based on the findings of several studies regarding the extension of survival after neoadjuvant radio chemotherapy in 15% of the patients to which the tumor stage has been reduced and followed by oncologic visa resection (8).

Also, approximately 60% of the pancreatic cancers have cephalic localization. Moreover, along with the decreasing of operatory mortality following duodenopancreatectomy, improved survival rates of 30% have been reported (9-12) that are three times higher than the previously published results (13-15).

However, the improvement of early results (decreased mortality, increased rate of resectability) and late results (long-term survival) are two different concerns and, seemingly, without a causal relationship between them.

In this way, some surgeons are not fully confident in these sudden improvements of the survival indices, hence it was suggested by some the requirement of the original diagnosis anatomopathological reconfirmation, and also other authors have proposed a standardized method of evaluation/ reporting of the survival data and identifying the subsets of patients (16).

Thus, in order to find out which subgroup of patients will have greater survival after resection; numerous studies analyzed and confirmed certain factors with prognostic value, such as the size and extension of the tumor, lymph nodes metastasis, the degree of differentiation of tumor cells and tumor involvement of the margins of resection.

Hence, by analyzing the parameters of survival, Han et al. have argued that the statistical evaluation method used is partic-

ularly important: the actual *vs.* the actuarial. In this way, if the data on survival do not contain 'censor date' - patients who have been lost in the follow-up or patients who were alive at the time of the study - there is no difference between actual and actuarial survival. However, this is almost impossible, considering the cases which inevitably are lost in the monitoring (17).

More than that, studies which contain patients who have survived more than five years, may overestimate the results, mainly due to the very nature of the Kaplan-Meier method. As a result, the aforementioned authors have reduced this source of error by selecting patients (n = 123) which have been resected at least 5 years prior to the study and have obtained a cumulative survival at 5 years of 12.1% and actual 5 years survival of 8.9% (11/123).

Comparing the previous data (5 years survival of 7.4%) obtained at their institution in 1986, the actual survival is similar in spite of the significant increase of resecability from 11.0% to 15.6% and the significant decrease of mortality (from 16.7% to 0.8%). Thus, it could not be stated that long-term survival after the resection for pancreatic cancer has dramatically improved (17).

In addition, Welch et al. group have studied the changes in terms of 5 year survival rate for 20 types of solid tumors by using the data from the National Cancer Institute from 1850-1995. They found minimal changes in terms of the 5 years survival rate (from 1% in 1950 to 4% in 1990) and suggested that the improved survival rate can be explained rather through early diagnosis than by reduced mortality by cancer (17).

Also, Yeo et al. conducted a very relevant study which included a group of 242 patients operated for periampullary vaterian adenocarcinoma at The Johns Hopkins Hospital. From these, 149 (62%) were pancreatic tumors, 46 (19%) were ampullary tumors, 30 (12%) distal bile duct cancer and 17 (7%) duodenal cancers. The surgical mortality was 5.3% along the 22-years review with 2% perioperative mortality for the last 100 patients. Also, the 5 years survival by type of tumor was as follows: for pancreatic cancer 15%, ampullary 39%, distal biliary route 27% and duodenal route 59%, while at 10 years survival was 5%, 25%, 21% and 59% respectively.

Moreover, the resected pancreatic tumors had an average diameter of 3 cm, 72% cases with ganglionic MTS and 31% with tumor positive resection margins (usually at the level of hepatic arteries and/or superior mesenteric artery). The average survival was of 12 months with the actual 5 year survival of 15% and actuarial 10 years survival of only 5%. Also, the survival continues to drop after 5 years, the later deaths being directly related to the tumor evolution, suggesting that the 5 years survival for the cancer of the pancreas is definitely not a cure (18).

Wagner et al. group has shown that curative resection is the only significant prognostic factor for survival (19). Moreover, the analysis of 650 consecutive pancreatic resections also showed that curative resection is an important factor influencing survival (20).

Geer et al. have reported the survival at 5 years of 245 from 246 resected patients while no patient of the 653 uneresected patients did survive for more than 5 years. They identified the ganglionic invasion, low tumor differentiation and tumor size > 2.5 cm as predicting factors (21).

Moreover, the group lead by Cameron et al. have reported survival at 5 years of 19% on a group of 89 resected patients and

have shown that the bad prognostic factors are the tumor related: size > 2 cm, presence of tumor adenopathies and vascular invasion (22), while Willet et al. have stressed the importance of performing pancreatic resections obtaining negative tumoral margins, a factor that has led to a 5 years actuarial survival of 22% compared to the 13% overall survival over the entire group (23).

Similar results have been also published by Trede et al. who analyzed the cases of pancreatic resections performed at Mannheim Surgical Clinic between 1972 and 1989. In this retrospective study the actuarial survival at 5 years was 24%. However, for the R0 and R1 resection the actuarial survival increased to 36%, and out of the 11 5-years survivors, 4 of them died due to the base disease (24, 25).

In addition, Baumel et al. conducted a multicenter retrospective study in France in order to analyze the short-term and long-term results of 787 pancreatic resections for cancer which were carried out between 1982 and 1988. The post operatory mortality was 10% and morbidity 35%. Moreover, the age over 70 years and the existence of an associated disease have affected the mortality rate. The median survival for patients who have been discharged was 12.3%, the 5 years actuarial survival was 12% - being lower, 4%, in patients with lymph node metastases as compared to those without ganglionic involvement - 20% (p=0.001).

Also, the surgical mortality was higher after total pancreatectomy than after cephalic duodenopancreatectomy (17% *vs.* 8%, p=0.015), while the median survival and the 5 years survival for total pancreatectomy and for duodeno-pancreat-ectomy was 11 *vs.* 14 months and respectively 3 *vs.* 15 months. Among the studied clinical and anatomopathological factors, the localization to the left of the tumor in the pancreas was strongly correlated with survival.

Duodenopancreatectomy remains the procedure of choice for pancreatic cancer, while total pancreatectomy is indicated only in patients with multifocal carcinoma or in those which cannot undergo a safe anastomosis (22).

Also in this area of research, Richter et al. argued that under the conditions of the resection of a pT1N0M0 tumor, the recurrence will occur, even if later, after 10 years. In fact, it is believed that the cancer of the pancreas is actually the cancer with the lowest 5 years survival rate. Moreover, Richter et al. assessed the long-term results from 194 patients who benefited from the standard Kausch-Whipple resection for pancreatic ductal cephalic adenocarcinoma. In this way, from the 194 patients, 56 patients (28.9%) required extensive venous resection due to the invasion of the portal vein, while 70% patients had a simple, complications free post operatory evolution, with the morbidity of 29.9% (58/194), and post operatory mortality of 3.1% (6/194).

Moreover, the hospital mortality rate was 3.6% (7/194). When confronting the pancreatic cancer patient, the surgeon actually has three options: a therapeutic 'nihilistic attitude', an 'aggressive', or a 'realistic' attitude. The nihilist advocates for a palliative treatment, non-resectable procedures even for resectable lesions, considering that patients will survive longer, with a superior quality of life, after a palliative by-pass than after a resection. Moreover, if taking into account the resections associated morbidity in comparison to that of palliative procedures, the cost-effectiveness ratio is in favor of palliation (23). Also, the aggressive surgical attitude involves a much more extensive, 'super-radical' resection: the total or regional

pancreatectomy with extensive lymphadenectomy regional based on the assumption that pancreatic neoplasm is a surgically curable disease only by extending the field of resection. Those advocating in favor of this attitude suggest even a more expanded lymphadenectomy: superior up the hepatic *hilum* and diaphragmatic hiatus, inferior to the AMI and laterally toward both renal *hila*. Still, until now no study published in literature has confirmed the positive effect of expanded lymphadenectomy on the prolongation of survival (24).

In addition to that, Yeo et al. has demonstrated, however, that expanded lymphadenectomy can be performed with morbidity and mortality similar to standard pancretectomy. However, in this case, the post operatory monitoring of patients from the studied group was too short (2 years) in order to draw meaningful conclusions (25).

Pedrazzoli et al. have confirmed that by extending the lymphadenectomy and the retroperitoneal tissue dissection *versus* standard operation does not increase post operatory morbidity and mortality (26).

Still, an improved effect on survival after extended lymphadenectomy has not been confirmed so far. In this way, by completing a retrospective nonrandom study, Ishikawa et al. compared the standard and the extended technique on 37 consecutive patients and found a year's survival rate of 13% after the standard technique *versus* the 38% following the extended lymphadenectomy (24).

Currently, the surgical mortality in specialized centers has decreased fewer than 5%, even with series of patients without mortality being reported (27, 28). Also, with the increasing number of patients surviving the pancreatic resections, an according increase in the number of the long-term survivors would be expected. However, in most centers the 5 years survival is reported around 5% (tab. I) (29).

TABLE I

5 years survival in some important international research centers

Study group	Institution	Patients (No.)	5-Year Survival (%)
Yeo	Johns Hopkins	201	21.0
Cooperman	Columbia (NY)	70	7.1
Lerut	Insel Spital Bern	25	6.0
Jones	Toronto	28	7.0
Grace	UCLA	37	3.0
Tsuchiya	Collective Japanese series (< 2 cm)	103	30.3
Connolly	Chicago University	89	3.4
Sarr	Mayo Clinic	104	10.0
Baumel	Coll. French series	555	15.0
Fong	Sloan Kettering (70 years)	138	21.0
Klempnauer	Hannover	107	13.8
Trede	Mannheim	122	25.4

Median survival in pancreatic cancer is 20 months for resectable disease, 9 to 12 months for locally advanced (unresectable) disease, and 5 to 7 months with metastatic

disease. Poor prognostic factors include advanced stage, poor performance status and peritoneal disease.

The 5-year survival rate of patient whose tumors were resected is poor; the reported range is 3% to 25%. The 5-year survival is 30% for patients with small tumors (less than 2 cm in diameter), 35% for patients with no residual tumor or for tumors did not require dissection from major vessel, and 55% for patients without lymph node metastasis (30). Performance status and the presence of four symptoms (dyspnea, anorexia, weight loss and xerostomia) appear to influence survival; patients with higher performance status and the lowest number of these symptoms lived longest. In non resectable or metastatic disease, median survival of patients with such disease is 2 to 6 months.

Sener et al. have analyzed the data of 44,438 patients, diagnosed with pancreatic cancer between 1985-1990, by using the national data base from the USA. In this way, the 5 years survival rate on decade of age in patients over 50 years has varied between 7.6 and 4.2% independently of the tumor location in the pancreas.

Also, after resection the 5 years survival was 23.3% for the patients without adjuvant therapy, 17.0% for the cases with resection, radio- and chemo-therapy, and 14.9% for those with pancreatectomy and radiation or chemotherapy.

On the other hand, the patients not receiving a specific treatment for cancer had a survival rate of 5.2%, which is similarly to those who were treated with radio- or chemotherapy, or both, but without resection.

In this way, the results of this study, similar to those of other studies, indicate that despite sophisticated post-operatory management and reduction of mortality for increasingly extended resections, there is no appreciable improvement in overall survival over the past two decades (31-33).

Thus, the general enthusiasm generated by the gastrointestinal tumors study group (GITSG) in 1987 on the use of radiotherapy in combination with 5-FU disappeared rather quickly (34). Also, further studies related to the use of high doses of radio +/- chemotherapy and the use of the neo-adjuvant radio chemotherapy have not demonstrated an increase of the 5 years survival rate, when compared with resection without other associated treatment. However this study has shown that the highest rate survival on tumoral stages was obtained after the tumor resection. Consequently, the resection should be performed when a low rate of complications will be achieved. It is also important that the diagnosis of pancreatic tumors even after resection, to be done with accuracy because the other periampullary tumors have a better prognosis and may alter the statistical results (35).

Nuzhat et al. have analyzed a sample of 125 patients operated for pancreatic ductal adenocarcinoma out of which 116 were completely monitored. The median survival after surgery was 16 months; the 1-, 3-, 5- and 7-year survival rate of for all patients was 60%, 23%, 19%, and 11% respectively. In addition, for the subgroup of resected patients receiving adjuvant therapy the 1-, 3-, 5-and 7-year survival rate was 69%, 28%, 23%, and 18% respectively, as compared to 20% and 0% for the patients not receiving adjuvant therapy ($p < 0.0001$).

Moreover, for the patients who had no tumor adenopathies the 1-, 3-, 5-and 7-year survival rate was 73%, 38%, 26% and 22% *vs.*52%, 14%, 14%, and 9% respectively in

the patients with ganglionic metastasis (p = 0.01). In fact, the multivariate analysis showed that adjuvant therapy was the only factor highly associated with survival (HR=0.26, 95%, CI=0.15-0.44). In this way, the 5 and 7 years overall survival of 19% and 11% highlight the data in the literature that surgical resection may increase long-term survival, particularly if associated with adjuvant chemoradiotherapy (36).

CONCLUSIONS

As mentioned, during the last decades the development and advance of the surgical methods and techniques have improved only morbidity and hospital postoperative mortality, without significant impact on survival. Thus, in the present paper we reviewed some modern aspects regarding the factors implicated in pancreatic cancer survival, in order to increase the awareness regarding this important pathology, which is considered to be the sixth or even fifth cause of death by cancer in most of the modern societies.

ECOCARDIOGRAPHIC EVALUATION OF ISCHEMIC MITRAL REGURGITATION IN PATIENTS WITH ACUTE MYOCARDIAL INFARCTION (Abstract). **Aim of the study:** echocardiographic evaluation of mitral regurgitation (MR) during the evolution of patients with acute myocardial infarction (MI). **Material and methods:** the study included 104 patients (73 males and 31 females), aged between 38-85, diagnosed with acute myocardial infarction (based on clinical, ECG and enzymatic evidences), in order to assess the MR (clinically - a new systolic murmur, and by echocardiography-the severity of MR). Echocardiography was performed upon admission and at 10-30 and 180 days after the onset of acute MI. The evaluation of MR was based on the following parameters: jet area, jet area indexed to left atrium, regurgitated volume, left atrial and left ventricular size, the evaluation of mitral valve apparatus in order to eliminate other possible causes of MR. **Results and discussion:** MR was found in 35 patients from 104 diagnosed with acute MI, as follows: severe in 20 patients (jet area > 8 square cm, jet area indexed to left atrium > 40%, regurgitated volume > 30 mL) and mild in 15 patients (jet area < 4 square cm, jet area indexed to left atrium < 20%, regurgitant volume < 30 mL). In 30 patients MR was produced by the dilatation of mitral annulus (because of the evolution to ischemic dilatative cardiomyopathy), 5 patients developed left ventricular aneurysm; in 3 patients, MR was produced by chordae rupture and in 2 patients we diagnosed an ischemic prolapse of posterior mitral leaflet. In evolution all the patients developed symptoms and signs of heart failure, and 2 patients were referred to surgery. **Conclusions:** The appearance of MR in the evolution of MI is an important sign of bad prognosis by its contribution to the appearance and/ or to the worsening course of heart failure. Mechanisms of this MR are very complex based on the alteration of left ventricular geometry. Echocardiography plays an essential role in the early diagnosis of MR, estimating its severity, the mechanisms and also the prognosis. **Keywords:** MITRAL REGURGITATION, ECHOCARDIOGRAPHY, ACUTE MYOCARDIAL INFARCTION

Chronic ischemic mitral regurgitation (IMR) is a common complication of myocardial infarction which severely affects cardiovascular mortality and morbidity (1, 3, 4). Multiple pathophysiologic mechanisms are involved in generating IMR, each of them having a different importance: left ventricular (LV) remodeling and dysfunction, annular dilation/dysfunction, and mechanical dyssynchrony (2, 3, 5). The most frequent mechanism involved in the occurrence of mitral regurgitation is the presence

of local or global LV remodeling that alters the geometrical relationship between the ventricle and valve apparatus (4, 5, 6, 8). In the wide spectrum of patients with chronic IMR, the assessment of some echocardiographic parameters, such as tethering pattern, leaflet motion, origin and direction of the regurgitant jets, allows one to identify different specific subgroups of patients subjected to different therapeutic approaches (2, 5, 6, 7). The aim of medical and/or surgical therapy is to improve heart failure symptoms, and improve LV remodeling and function and the intermediate/long-term outcome. The targets of surgical MV repair involve annulus, leaflets, chordae and ventricles (9, 10, 11) The restricted annulo-plasty is the most commonly adopted surgical procedure that improves heart failure symptoms but not survival when compared to medical therapy and is also subject to a high incidence of late failure (~30%) (9, 11).

The aim of the study was to evaluate the possible mechanisms involved in the occurrence of mitral regurgitation in patients with acute myocardial infarction.

MATERIAL AND METHODS

The study included 104 patients, 73 (70,19%) males and 31 (29,8%) females, aged between 38-89 years, admitted to the 1st Cardiology Clinic between 2003 and 2012, diagnosed with acute myocardial infarction. All patients were admitted to the emergency unit of the hospital and they were brought by ambulance in most of the cases.

We selected in our study patients who fulfilled diagnostic criteria for acute coronary syndrome:

- clinical symptoms-angina;
- paraclinical tests: electrocardiographic ST changes associated with subendocardial or subepicardial ischemia or new left bundle branch block *(*LBBB) associated with high levels of myocardial cytolytic enzymes (Troponin).

Paraclinical evaluation included:

- evaluation of the risk factors: level of glucose, uric acid, lipid profile, complete blood count, coagulation tests;
- medical tests that evaluate the main organs affected by high blood pressure or/and diabetes;
- 12-lead electrocardiogram - for positive diagnosis and localization of acute coronary syndrome;
- Echocardiogram (2D, M-mode and Doppler) - to assess systolicand diastolic function of LV; regional kinetic changes, the presence of other complications (intracavitary thrombus), and in order to detect mitral regurgitation (the aim of the current study).

RESULTS AND DISCUSSION

The diagnosis of myocardial infarction was established by: clinical typical symptoms, electrocardiographic changes, elevation of myocardial cytolysis enzymes and in few cases-pathological confirmations. Being a major emergency, the first therapeutic measures for all patients were initiated in the emergency care unit concomitant with a cardiologic examination.

The following steps were undertaken: the anamnesis of the patient, with the mention that in the situations in which the condition of the patient did not allow the direct anamnesis, the data was obtained from his relatives or from the previous hospital release documents (patient's previous medical folder respectively).

The following aspects were investigated during the anamnesis:

- patient's cardiovascular antecedents:

high values of blood pressure (HBP), chronic ischemic disease, acute myocardial infarction (IMA), valvular heart diseases, dilated cardiomyopathy (CMD), previously known rhythm and/or conduction disorders, potential surgical interventions at the level of the cardiovascular system;

- the associated risk factors having an impact on the cardiovascular system (smoking, alcohol intake, diabetes);

- associated co morbidities (thyroid gland disorders such as hypo or hyperthyroidism, chronic obstructive bronchopneumopathy (BPCO), stroke);

- treatments followed at home up to the moment of coming to the emergency care unit;

- the emphasis was on identifying the precipitating and aggravating factors of the acute MI: inadequate physical effort, alcohol intake, paroxysmal rhythm disorder, conduction disorder, prolonged treatment discontinuation, excessive salt intake.

The complete examination of the patients involved: assessing the general state, consciousness, pulmonary auscultation, heart and peripheral arteries (carotid) auscultation, checking of blood pressure (BP).

All patients were monitored in the coronary intensive care unit (ECG, breaths/ minute, BP, O_2 sat, diuresis).

Standard 12-lead ECG was performed on all patients immediately after admission to confirm the diagnosis of acute myocardial infarction, the localization of MI and possible arrhythmic complications.

The localization of myocardial infarction in the patients from the group was: anterior - 57 (51.92%) cases; inferior - 23 (22.11%) cases; antero-extensive - 15 (14,42%) cases; infero-lateral and right ventricular infarction - 9 (8,65%) cases (fig.1).

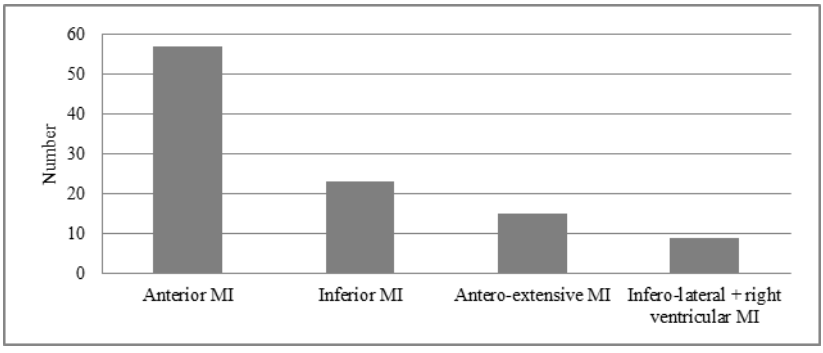

Fig. 1. Localization of myocardial infarction

The analysis of the associated risk factors in the patients from the group revealed the following: of the total number of patients, 31 (29.8%) were smokers, 23 (22.11%) reported chronic alcohol consumption, dyslipidemia was present in 48 (46.15%) patients, 6 (5.76%) of them being under treatment with statin. Diabetes was present in 11 (10.57%) males and 8 (7.69%) females, 5 (26.31%) of them being under treatment with insulin; 3 (2.88%) patients had associated thyroid pathology; 4 (3.84%) of them had antecedents of stroke; 15 (14.42%) had chronic obstructive bronchopneumopathy (BPCO) and 4 (3.84%) presented chronic renal disease (fig. 2).

From all the patients 85 (81.73%) had a history of previous angina.

The clinical examination was focused on the discovery of a mitral regurgitation murmur in patients with acute MI during the evolution.

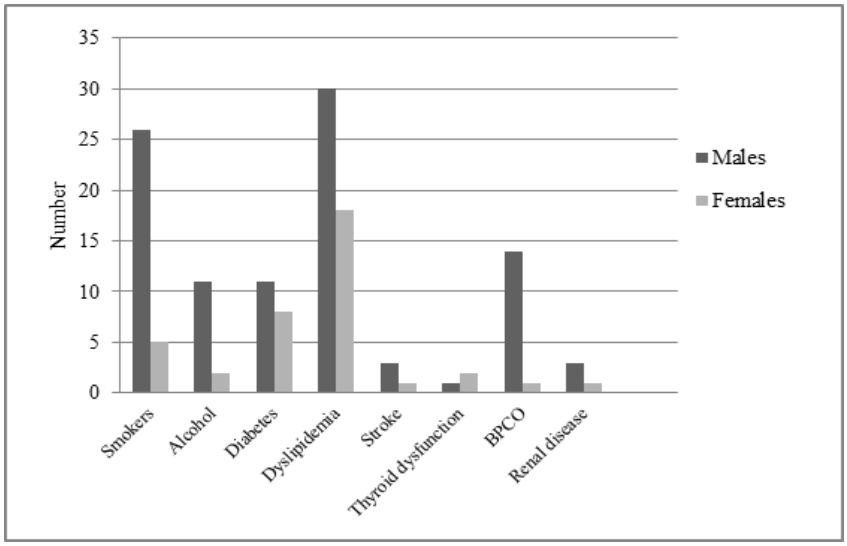

Fig. 2. Risk factors present in the patients diagnosed with acute myocardial infarction.

After confirming mitral regurgitation by echocardiography, the following parameters were determined:

- jet area;
- jet area indexed to left atrium;
- regurgitant volume;
- left atrial and left ventricular size;
- the evaluation of mitral valve apparatus in order to eliminate other possible causes.

Echocardiography 2D, M-mode and Doppler was performed in all patients upon admission and thereafter depending on the situation, 10, 30 and 180 days after onset.

Mitral regurgitation was found in 35 (33.65%) patients from 104 diagnosed with acute MI, as follows: - severe in 20 (19.23%) patients - jet area > 8 square cm jet area indexed to left atrium > 40%, regurgitant volume > 30 mL and mild in 15 patients (14.42%) - jet area < 4 square cm, jet area indexed to left atrium < 20%, regurgitant volume < 30 mL (fig. 3).

The etiology of mitral regurgitation was also estimated by echocardiography as follows:

- in 30 (28.84%) patients echocardiography showed dilatation of mitral annulus (because of the evolution to ischemic dilatative cardiomyopathy), 5 (4.80%) patients developed left ventricular apical aneurysm;
- 3 (2.88%) patients-chordae rupture;
- 2 (1.92%) patients -ischemic prolapse of posterior mitral leaflet (fig. 4).

The localization of the acute MI in patients who develop acute mitral regurgitation was:

- 25 (24%) of patients: anterior myocardial infarction;
- 5 (4.80%) patients: anterior extensive MI;
- 2 (1.92%) patients: inferior MI;
- 3 (2.88%) patients: infero-lateral MI (fig. 5).

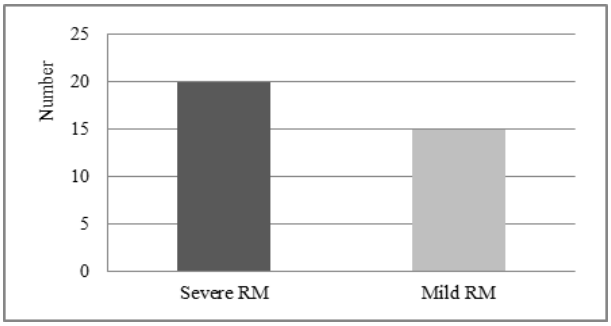

Fig. 3. Classification of mitral regurgitation

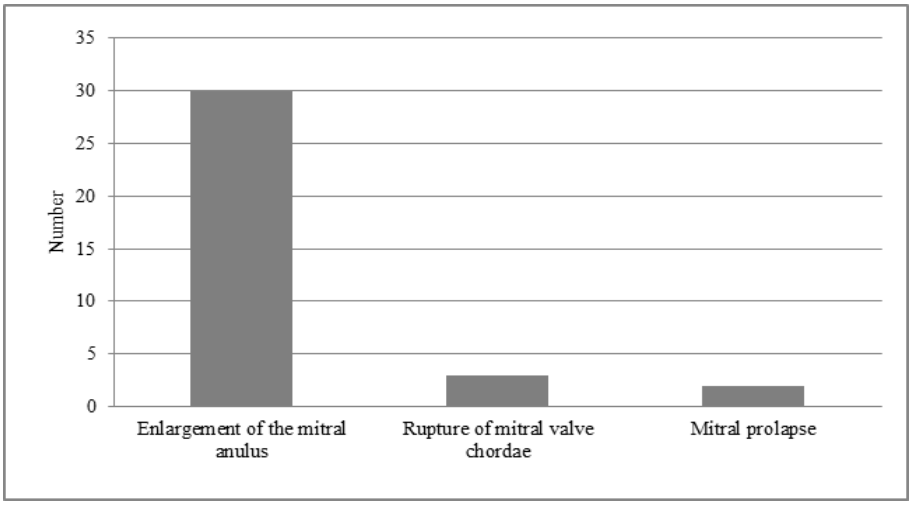

Fig. 4. Causes of mitral regurgitation

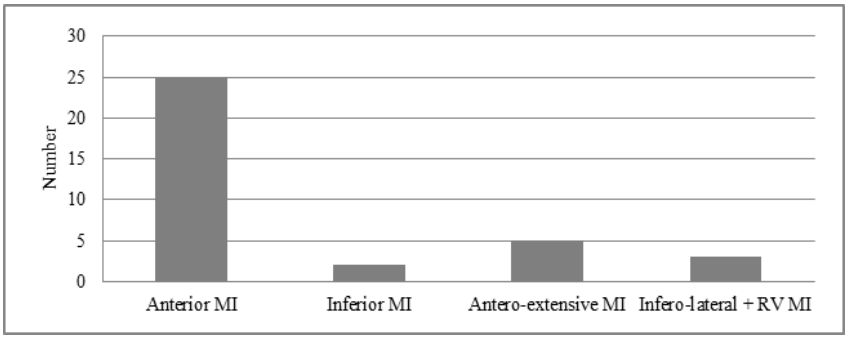

Fig. 5. Localization of acute MI in patients with MR

The evolution of patients from study who developed mitral regurgitation by different mechanisms during evolution of myocardial infarction was:

- all the patients developed symptoms and signs of heart failure;

- 2 (1.92%) patients were directed to cardiac surgery for valvular reconstruction;
- 2 (1.92%) patients (one female and one male) died from cardiogenic shock.

CONCLUSIONS

The appearance of MR in the evolution of myocardial infarction is an important sign of bad prognosis by its contribution to the appearance and/or to the worsening course of heart failure. Mechanisms of this MR are very complex based on the alteration of left ventricular geometry. In our study the principal mechanism was the dilatation of mitral annulus (because of the evolution to ischemic dilatative cardiomyopathy), followed by chordae rupture and ischemic prolapse of posterior mitral leaflet. Echocardiography plays an essential role in the early diagnosis of MR, estimating its severity, the mechanisms and also the prognosis.

HYPONATREMIA – RISK FACTOR IN PATIENTS WITH CHRONIC HEART FAILURE – CLINICAL, EVOLUTIVE AND THERAPEUTIC IMPLICATIONS (Abstract): Patients with heart failure are, by definition, hemodynamically unstable. This condition may be accentuated by medication (digitalis, diuretics, antiarrhythmics), so that they become more sensitive to electrolyte disturbances. Hyponatremia is the most common electrolyte disorder, particularly common in the intensive care unit. **Aim:**the evaluation of the incidence of hyponatremia in patients diagnosed with chronic heart failure in order to establish a correlation with the evolution, prognosis and therapeutic implications. **Material and methods:** We analyzed retrospectively 120 patients diagnosed with chronic heart failure NYHA II-IV classes, admitted in the Cardiology Clinic between 2009 and 2013. We analyzed electrolytic disturbances which occurred during different strategies of therapy. **Results:** 120 patients with heart failure were admitted in the Cardiology Clinic between 2009 and 2013, 92 males and 28 females. Diagnosis was established by classical criteria. Evaluation was very complex and included: complete clinical examination, electrocardiogram, echocardiography, chest ray examination and biochemical analyses especially hepatic, renal function and electrolyte status. **Conclusions:** The data obtained showed that electrolyte disturbances are frequent in patients with chronic heart failure, irrespective of NYHA class. Hyponatremia is usually associated with diuretic therapy and may play a very important role in the subsequent development of life-threatening complications. Patients with heart failure who develop hyponatremia during their evolution had a worse prognosis. **Keywords:** ELECTROLYTE DISTURBANCES, HYPONATREMIA, HEART FAILURE

The patient with heart failure (independent of etiology) is, by definition, a hemodynamically unstable patient in which a therapeutic plan, initially beneficial, may have unexpected side effects, some of them life-threatening (1). This type of patient usually has an electrical and hemodynamic instability related to the underlying disease and potentiated by complications and also by medication (diuretics, digitalis, antiarrhythmics) (1, 2, 3). In these conditions, patients become more sensitive to even minor elec-

trolyte balance disturbances, sometimes reacting violently through serious arrhythmias or conduction disturbances. Despite the advanced therapies of heart failure, the significant associated morbidity or mortality due to complex side effects of therapy was not reduced. The medication of the patient with heart failure involves a complex therapeutic schedule. The diuretic medication is essential and it is path physiologically addressed to the salt and water retention (3). Although well tolerated by most patients, diuretic medication acting at renal level disrupts the electrolyte balance so that, depending on the type of mechanism, on the patients' condition at the time, on the associated medication and diet, there may appear other electrolyte and fluid disorders, some of which could be life-threatening (1, 2, 3). Hyponatremia is the most common electrolyte disorder in intensive care units (its frequency is estimated at 30-40% of the hospitalized patients) (4, 5, 6). Hypervolemic hyponatremia, especially, is associated with a bad prognosis in patients with heart failure.

The aim of the study is to evaluate the incidence of hyponatremia encountered in patients with heart failure and to establish a correlation between this disorder and the occurrence of certain complications, and the entailed prognosis and therapeutic implications.

MATERIAL AND METHODS

The study is retrospective and included a group of 120 patients, 92 men (76.66%) and 28 women (23.33%), aged 48-85 years, hospitalized in the 1st Cardiology Clinic between the years 2009-2013 and diagnosed with chronic heart failure of the NYHA II-IV classes.

The classification of patients in the NYHA class of severity of heart failure was as follows:

- NYHA Class II - 19 patients: 10 men, 9 women;
- NYHA class III - 82 patients: 65 men, 17 women
- NYHA Class IV - 19 patients: 14 men, 5 women

The diagnosis of heart failure was based on the known and classical clinical and paraclinical data:

- Symptoms and signs of left ventricular failure (shortness of breath of different degrees, cardiac cough, tachycardia with / without gallop rhythm, presence of organic heart breaths and pulmonary rales stasis);

- Signs of right heart failure: hepatomegaly, peripheral edema (cardiac type), turgid jugular (level I-III), hepatojugular reflux, with or without ascites.

Paraclinical exploration of the patients included:

- Chest radiography - objectified cardiomegaly (ICT over 0.55) with or without signs of pulmonary stasis or pleural effusions.

- Echocardiography (2D, M mode, Doppler) objectified cardiac cavities dilation with decreased contractile function parameters (ejection fraction, shortening fraction), and other aspects: valvular regurgitation, intracardiacthrombus, and presence of spontaneous contrast and signs of hypertension pulmonary artery. Echocardiography was essential for identifying the etiology of heart failure.

- Peripheral venous pressure was elevated in most patients with right heart failure component.

- 12 leads surface ECG, in which these were sought: rhythm or management disturbances, ischemo-lesional changes, overstress of certain cavities, changes due to

electrolyte disturbances.

- Biochemical balance included: hepatic function (transaminases, bilirubin, GGT), renal function (urea, creatinine, uric acid, creatinine clearance, RA), serum electrolytes (Na^+, K^+, $Ca^{+2,}$ Mg^{+2});

- Paraclinical investigation was complemented with complete blood count, spirogram and determination of blood gases and pH.

Patient evaluation was performed first at the time of admission and subsequently, depending on each particular case, was performed daily during hospitalization.

The etiology of heart failure was as follows:

- Ischemic dilated cardiomyopathy - in 30% of cases;

- Ethanolic dilated cardiomyopathy - in 35% of cases;

- Mixed dilated cardiomyopathy (ischemic, toxic, diabetic) - 20% of cases.

- Valvular heart disease - 15% of cases.

Etiology was based on personal history, physical examination and echocardiographic data resulted from examination. In some cases, the presence of the biochemical markers that supported chronic alcoholism was added to these.

Patients' treatment was strictly individualized according to the hemodynamic status at the time of hospitalization, the etiological features, the presence or absence of arrhythmias and/or conduction disturbances and included, besides the appropriate hygienic-dietary measures, the following:

- Diuretic: loop – 15% of patients, spironolactone + loop diuretic combination - 85% of patients;

- Nitrate type vasodilator - 75% of patients;

- Converting enzyme inhibitor (ACEI) - adjusted doses of TA- was administered to 85% of patients (65% received perindopril, 20% received ramipril);

- Beta blocker - 90% of patients (55% carvedilol, bisoprolol 35%);

- Digoxin - 45% of patients;

- Amiodarone - 30% of patients;

- Anticoagulant - 65% of patients;

- Antiplatelet - 75% of patients received aspirin (in 50% of the cases it was associated with an anticoagulant), 28% of patients receiving clopidogrel.

- Dopamine (vasodilator dose) was necessary in 35% of cases because of signs of low cardiac output or renal failure.

Patients received therapeutic regimens that included combinations tailored to each individual case, as follows:

- Loop diuretic + vasodilator (nitrate) + beta blocker + ACE inhibitor - 15% of cases;

- Loop diuretic + spironolactone + ACE inhibitor + beta blocker + vasodilator (nitrate) - 40% of cases;

- Loop diuretic + spironolactone + ACE inhibitor + beta blocker + digoxin + vasodilator - 20% of cases;

- Loop diuretic + ACE inhibitor + amiodarone + vasodilator - 25% of cases.

All patients received an antiplatelet regimen and in 65% of the cases an anticoagulant administration was necessary.

Introducing the anticoagulant regimen was imposed by the presence of echocardiographic intracavitary thrombus or spontaneous contrast, by the presence of dilated right cavities and other clinical signs suggestive of thromboembolism associated phenomena. Throughout the immobilization in bed prophylactic doses of low molecular weight heparinwere also injected.

The nitrate type vasodilator (small doses) was used with preference in patients

with signs of left ventricular failure considered to be due to ischemia and in patients with evident pulmonary stasis with normal values of arterial blood pressure.

RESULTS AND DISCUSSION

120 patients, 92 men and 28 women, aged between 48-85 years and diagnosed with chronic heart failure of the NYHA II-IV classes were hospitalized in the 1st Cardiology Clinic between 2009 and 2013.

Most of the patients were male and were included in NYHA class III - 82 patients (68.33%), (65 men and 17 women). 19 patients (15.83%) were included in NYHA Class IV (14 men, 5 women).

Hyponatremia (serum sodium values between 128-110 mmol/l) was present in all patients with NYHA IV class heart failure receiving diuretic therapy.

From the NYHA III class of heart failure only 35 patients (42.68%) developed hyponatremia after diuretic therapy. Clinically, these patients presented generalized oedema upon admission.

The etiology of heart failure was: dilated cardiomyopathy (ethanolic or ischemic) and valvular heart disease.

All the patients were previously treated with diuretics (loop diuretics alone or in combination with spironolactone). In 5% of cases, hyponatremia persisted after stopping the administration of the diuretic, so it was considered dilution hyponatremia and significantly correlated with increased mortality in this group.

The correction of hyponatremia was difficult, with partial response, limited to fluid restriction and administration of sodium chloride, while continuing the diuretic. In 10% of cases, the patients developed symptoms and signs of brain oedema (disorientation, seizures, confusion, lethargy). Neurological symptoms were correlated with serum sodium values under 120 mmol/l. Gastrointestinal symptoms were present in all the patients: anorexia, nausea, vomiting. In 20% of case signs of neuromuscular damage were present: muscle cramps, generalised weakness. Persistent and refractory hyponatremia was associated in our study with a great incidence of malignant ventricular arrhythmias (ventricular tachycardia and fibrillation). These arrhythmic complications determined the revaluation of the therapeutic plan.

The occurrence of hyponatremia was followed by the impossibility of continuing the administration of diuretic therapy that still remained necessary in the presence of generalized oedema.

In 15% of cases, these electrolyte disturbances have been associated with inflection of the renal function, that is, increased urea and creatinine values understood as renal functional failure and whose main cause was the diuretic abuse with subsequent reduction in pressure renal perfusion. In 7% of cases, renal failure was corrected by temporary withdrawal of the diuretic and proper hydration. In 35% of cases, the administration of vasodilator dose dopamine was necessary (2-3 mcg/kg/min).The final prognosis was worse, 25% of patients died during hospitalization. The main causes of death were: asystole and ventricular malignant arrhythmias.

CONCLUSIONS

Electrolyte disturbances are common in patients with heart failure, regardless of NYHA functional class. In most cases this is due to medication, especially to the diuretic therapy. Hyponatremia is an independent negative prognostic factor especially in patients enrolled in the NYHA IV

functional class and it is often associated with increased mortality. The correction of hyponatremiais very difficult, with partial response, limited to fluid restriction and administration of sodium chloride. The treatment of hyponatremia can lead to potentially dangerous complications. It is essential to monitor the serum sodium level daily in patients with heart failure and a high risk to develop hyponatremia.

NEWS

NEW TREATMENT FOR MULTIDRUG-RESISTANT TUBERCULOSIS

Tuberculosis (TB) is an infectious disease with high morbidity and mortality. Difficulties related to the diagnosis and treatment of TB have increased incidence of multidrug-resistant tuberculosis (MDR-TB). Management of MDR-TB cases is more difficult because the treatment is longer, less potent, more toxic and more expensive, and determines a cure rate very low and a relapse rate very high. In this situation, the development of novel anti-tubercular drugs has become a necessity. Bedaquiline known as TM207 or R207910 is a diarylquinoline that inhibit synthesis of adenosine triphosphate (ATP) by specific binding to bacterial ATP synthetase. This new compound is active against sensitive and resistant strain of *Mycobacterium*, replicating or dormant bacteria. Clinical trials in MDR-TB patients conducted in South Africa revealed that bedaquiline (400 mg daily for 2 weeks and then 200 mg three times a week, in oral administration) has an early bactericidal activity similar to rifampicin and isoniazid, increased the rate of sputum conversion and also decreased the time for sputum conversion. The same study showed that the most common side effects caused by bedaquiline were: nausea, increase QT interval and the level of transaminases. United States Food and Drug Administration approved bedaquiline for treatment of MDR-TB, when no other drug is available. World Health Organization recommends bedaquiline for adult patients with pulmonary MDR-TB, but also argues the need for the studies about long-term safety (Goel D. Bedaquiline: A novel drug to combat multiple drug-resistant tuberculosis. *J Pharmacol Pharmacothe*r. 2014 Jan;5(1):76-8. doi: 10.4103/0976-500X.124435).

PSORIATIC RHEUMATISM. INFLAMMATORY ARTHROPATHY

Luana Macovei[1], Isabella Brujbu[2]

Faculty of Medicine
1. Discipline of Rheumatology-Balneophysiotherapy
2. Discipline of Family Medicine

PSORIATIC RHEUMATISM. INFLAMMATORY ARTHROPATHY (Abstract): Psoriatic rheumatism is an inflammatory arthropathy associated with cutaneous psoriasis that occurs mainly in adults aged between 30 and 45 years. In most cases, cutaneous phenomena precede rheumatic manifestations. Psoriatic rheumatism may begin as a monoarthritis and the diagnosis will be confirmed by the presence of psoriatic plaques or by the personal and family history of psoriasis. As a chronic proliferative epidermal disease, psoriasis is due to a genetic predisposition and it is clinically expressed following the triggering action of several factors. The onset is preceded by various events. Psoriasis is two to three times more common in patients with arthritis and about 10-20% of psoriasis patients show joint damage. **Aim:** The present study aims to demonstrate the clinical and biological efficacy of biotechnology-derived biologic drugs, acting as TNFα antagonists and used as backup therapy, at the same time bringing new hope for broadening and improving therapy in psoriatic arthropathy. **Material and methods:** The study included a total of 21 patients (13 men, 8 women) admitted in the interval 2011-2012 to the I-st Rheumatology Clinic of the Iasi Rehabilitation Hospital. The patients were older than 20 years and had one or more peripheral arthritis conditions, skin and nail lesions. **Results and discussion:** Based on the results, it is recommended that infliximab to be administered in patients who meet CASPAR ((Classification Criteria for Psoriatic Arthritis) diagnostic criteria, have the disease in aggressive stage, and do not respond to treatment with methotrexate (MTX) or other disease-modifying antirheumatic drugs - DMARDs (leflunomide, sulfasalazine) administered for 12 weeks. **Conclusions**: Infliximab is effective in counteracting the potentially harmful elements. It reduces the number of tender and swollen joints, improves the functional capacity and the quality of life, and slows down the radiologic progression. Infliximab is well tolerated, effective, with an optimum safety profile during short-term administration in patients with active forms of psoriatic arthropathy. **Keywords:** INFLAMMATORY ARTHROPATHY, CLINICAL MANIFESTATIONS, EARLY DIAGNOSIS, DIAGNOSTIC CRITERIA.

Psoriatic arthropathy (PA) is a chronic rheumatic inflammatory disease (1) with immunological determinism, causing a combination of two types of damage: *articular* – arthritis (2) and *cutaneous* – vulgar psoriasis (3); the articular damage is of polyarticular type; immunological tests (rheumatoid factor, anti-cyclic citrullinated peptide antibodies - anti-CCP) are usually negative. Prevalence of the disease ranges between 0.1 and 1%. It occurs in about one third of patients affected by cutaneous

psoriasis and is equally distributed between sexes. PA is known to have an erosive and destructive potential in approximately 40-60% of patients (4) and a progressive development even from the first year of diagnosis. Psoriatic arthropathy may cause chronic joint damage, severe functional impairment, leading to significant social and medical costs (5).

The analysis of family distribution (10-20%) reveals the role of heredity, but viral, bacillary, immunological, psychogenic and metabolic factors are also involved. Of the numerous suggested hypotheses, the only universally accepted are the *hereditary* and *metabolic* ones (5, 6).

Monoarticular or polyarticular manifestations of inflammatory nature commonly affect the distal interphalangeal joints of the fingers or toes: their integuments become shiny, look like sausage fingers and the nails show typical lesions, such as penetrated grooved nails and even onycholysis. Misalignment and deformity occur late and cause major functional impairment. This broad clinical spectrum also involves many tissues other than skin and nails, including the synovial membrane, cartilage, bone, entheses, and tendon. The symptoms of the disease can range from minimal entheseal pain to arthritis mutilans, the most destructive form of arthritis.

Besides these peripheral asymmetric articular manifestations affecting both the large joints of the limbs and the medium and small ones, the axial segment may also be affected. There may be also unilateral or asymmetric sacroiliitis or segmental spinal cervical locations and often cervical locations, where ossifications typical to seronegative arthritis coexist with treatment-resistant skin and scalp lesions with poor prognosis. The concomitant involvement of large peripheral joints occurs as asymmetric subacute arthritis, evolving to complete rigidity and stiffness.

Laboratory investigations indicate the absence of rheumatoid factor (which is also a diagnostic criteria), increased ESR and CRP. Major increases of these values characterize the polyarticular forms resembling rheumatoid arthritis, and are associated with the progression of joint disease, early mortality, and erosive and destructive potential (protein blood count, anemia, leukocytosis).

The radiologic exam shows signs of erosive arthritis located at a distal interphalangeal level, with simultaneous presence of proliferation phenomena, bone lysis and ankylosis, unilateral or asymmetric sacroiliiitis and vertebral parasyndesmophyte that affect mostly the upper cervical spine (C2-C3) (6).

Due to its clinical heterogeneity, psoriatic arthritis is sometimes difficult to diagnose, especially in the absence of cutaneous lesions. The clinical course of psoriatic arthropathy may be silent and benign, but many patients may have a severe and sometimes debilitating course that requires early diagnosis.

Our study aims to prove the clinical and biological effectiveness of the therapy with biotechnology-derived drugs that act as cytokine antagonists (TNFα) and are used as backup therapy, but at the same time it brings new hope for broadening and improving therapy in PA.

MATERIAL AND METHODS

The study included total of 21 patients (13 men, 8 women) admitted in the period 2011-2012 to the I-st Rheumatology Clinic of Rehabilitation Hospital Iasi. The patients were aged over 20 years and had one or

more peripheral arthritis conditions, skin and nail lesions.

The following parameters were analyzed: *demographic characteristics* (the mean age of the study group patients was 47.0 ± 2.1 years and the mean duration of articular symptoms 4.2 ± 1.3 years), *personal and family medical history*, *case distribution after the onset of disease*, *clinical manifestations* (axial syndrome, peripheral articular syndrome, enthesopathic syndrome, and extra-articular syndrome), *patient self-assessment* (duration of morning stiffness, pain intensity, and global assessment of disease activity), *evaluation parameters* (joint pain, joint swelling, dactyly, enthesis index, thoracic expansion, Schober's test, finger-ground distance and overall assessment of PA activity), *evaluation of the psoriatic skin lesions* performed by a dermatologist, *laboratory investigations* (hand radiographs, pelvis radiograph for imaging sacroiliac joints, radiograph of cervical dorsal lumbar spine, for assessing the stage of disease), *nonspecific inflammation tests* (ESR by Westergren method, CRP dosage by nephelometry), *assessment of rheumatoid factor* by ELISA and latex assays, *analysis of HLA histocompatibility system*, *immunological abnormalities*, *antibody analysis*, *the type of treatment*, *early clinical and biological evaluation after 6 weeks*.

RESULTS AND DISCUSSION

In our study group, the onset was manifested by psoriatic lesions (72% of cases). The rest of the cases subsequently developed arthritis. Nail damage was present in 50% of cases, as onycholysis, the "oil stain" appearance of the proximity of the nail bed, hyperkeratosis.

Men were mostly affected: 13 men (61.90%) to 8 women (38.09%). The mean age of patients included in the study group was 47.0 ± 2.1 years and the mean duration of articular symptoms was 4.2 ± 1.3 years (fig.1).

There is a familial aggregation of the disease, as it is more common in patients whose blood relatives have psoriatic arthritis.

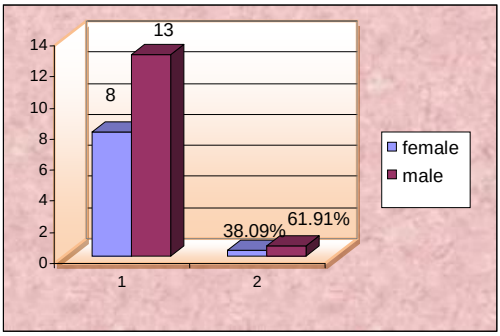

Fig. 1. *Sex distribution of the study group*

The onset was more often in the fourth decade of life, and the peak incidence was in the fifth decade of life, mainly in women.

The conclusion was that the onset of psoriasis can occur at any age, but it was more common in the third and fourth decade of life (fig. 2).

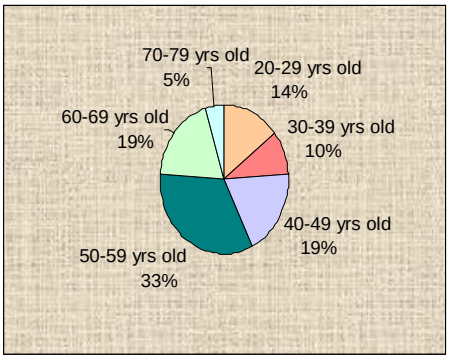

Fig. 2. *Age distribution of the study group*

Psoriatic arthritis has occurred mostly

in rural patients (63%) as compared to urban patients (37%), which can be explained by different education levels and insufficient prevention campaigns (fig. 3).

The onset of the disease may include both characteristic articular manifestations and integumentary lesions. The study group mainly presented psoriatic lesions (62%) and arthritis has occurred subsequently. In 7% of PA patients, the onset of psoriatic lesions was simultaneous with that of arthritis (fig. 4).

HLA B27 antigen was present in a significant proportion of PA patients (45%). HLA B38 and B39 antigens are found in patients with peripheral arthritis, and HLA DR 4 antigen (6%) causes the association of psoriasis with arthritis.

Significant increases in ESR levels are correlated with the progression of articular disease and early mortality. PA caused in two thirds of cases a severe biological inflammatory syndrome (CRP), and in one third of cases the values were moderate and correlated with the erosive and destructive potential, but not with the disease activity.

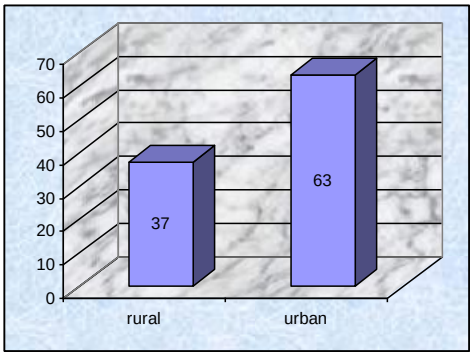

Fig.3. *Area distribution of psoriatic arthropathy study group*

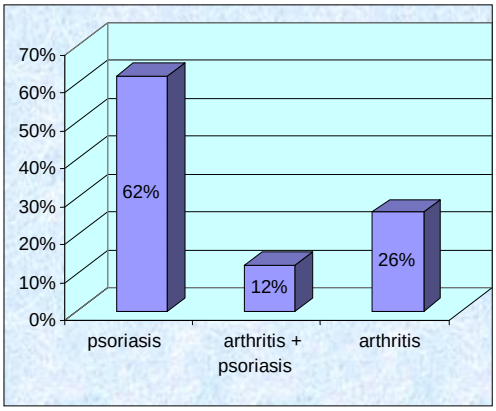

Fig.4. *Onset distribution of the study group*

In our study, PA was the most common joint disorder and manifested as an acute or subacute oligoarthritis affecting large or small joints (hand joints), with inflammatory phenomena in the characteristic subacute forms that are painful and integuments are under tension.

Except for the spine, the inflammatory process affected peripheral joints, periosteum, along the tendons and on the bone insertion of tendons.

Distal interphalangeal joints were mostly damaged. Ankle and knee joints showed asymmetric changes and DIP and PIP joint damage was associated with enthesitis that lead to dactylitis.

The study group had classic lesions of psoriasis vulgaris on the scalp (10%), upper limbs (35%), lower limbs (25%), and trunk (30%). Typical lesions of psoriasis include erythematous plaques that are well-defined, round-to-oval, covered with multi-layered silvery white lamellar scales, that are easy to remove and in a healing process, or covered with thick scales and peeling skin on the damaged areas. Skin erythema and infiltration may also be present (fig. 6).

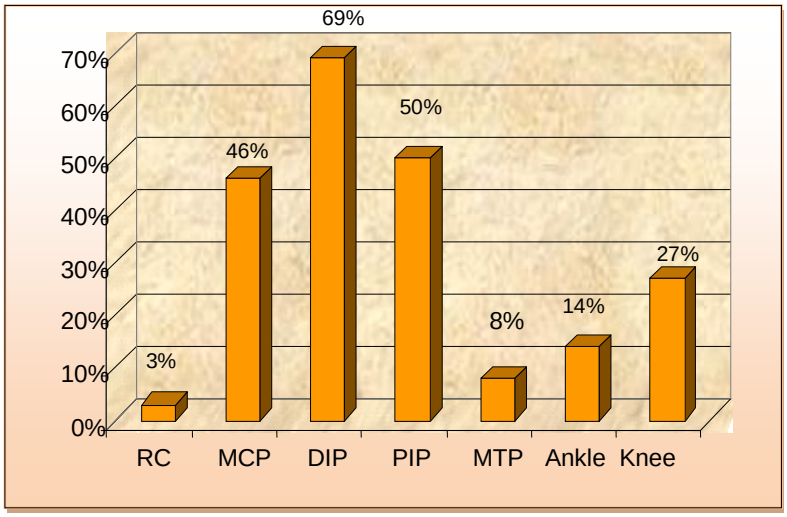

Fig. 5. *Distribution of the type of damaged joints in the study group*

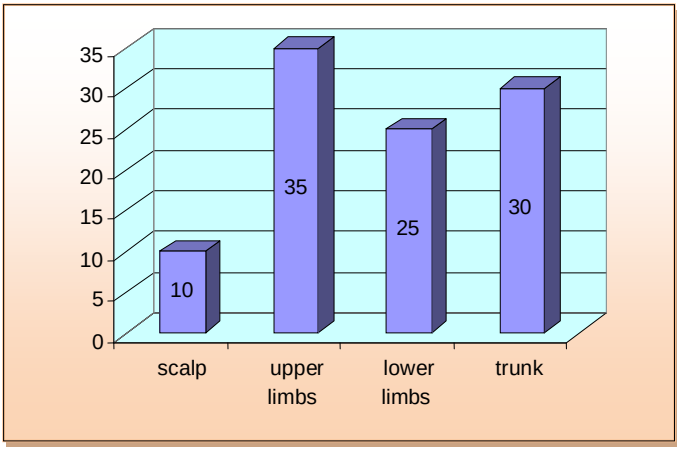

Fig. 6. *Distribution of the psoriatic skin lesions in the study group*

Nail changes were present in 95% of the study patients. These included transverse ridges, punctiform depressions, onycholysis, and nail calcification. The patients with no nail changes were younger or the disease was in an early stage.

Sacroiliitis with axial development occurred mainly in men with HLA 27 antigen (65% of cases), suggesting that the disease has developed for several years.

All patients had morning joint stiffness of variable intensity and duration.

Normal therapeutic course

The effectiveness and safety of infliximab therapy was studied in 21 patients with active polyarticular PA (≥ 5 swollen joints, ≥ 5 tender joints), using 5mg/kbw every 8 weeks. The response to treatment was assessed by measuring changes in the

number of swollen and tender joints, acute phase reactants, the overall assessment of health status by patient and doctor.

The clinical criteria were assessed based on parameters that define the development of the disease (swollen and tender joints, morning stiffness, etc.). An improvement of 75% to 90% was found during treatment.

When a decrease in inflammatory phenomena was achieved, the therapeutic process was supplemented with the interest in the psychological state of the patient, who should be encouraged to reestablish social contacts and to show interest in various activities.

MTX (methotrexate) in association with other drugs is superior to MTX alone. The compliance to polytherapy was optimal, with limited adverse effects, and the functional status of the patients was significantly improved.

Based on the results, it is recommended that infliximab to be administered in patients who meet CASPAR diagnostic criteria (Classification Criteria for Psoriatic Arthritis, developed by W Taylor et al. in 2006), have the disease in aggressive stage, and do not respond to treatment with methotrexate (MTX) or other disease-modifying antirheumatic drugs (DMARDs) administered for 12 weeks.

TABLE I

Effectiveness of therapy with Infliximab + MTX according to ACR criteria

Drug	ACR 20
MTX + Infliximab 3mg /kg	49%
MTX +Infliximab 5mg /kg	53%

CONCLUSIONS

Infliximab is effective in counteracting the potentially harmful elements. It reduces the number of tender and swollen joints, improves the functional capacity and the quality of life, and slows down the radiologic progression. Infliximab is well tolerated, effective, with an optimum safety profile during short-term administration in patients with active forms of psoriatic arthropathy.

The clinical assessment showed that the risk of premature death was closely related to the activity and severity of arthritis and to the presence of radiological erosions and to high levels of ESR.

POSTOPERATIVE INFECTIONS IN PATIENTS WITH TOTAL HIP OR KNEE ARTHROPLASTY - INVOLVEMENT OF ALLOGENEIC BLOOD TRANSFUSIONS

Up to 70% of patients who undergo total hip or total knee arthroplasty receive blood transfusions. A recent study conducted by Friedman and co. investigated whether allogeneic blood transfusion increases the risk of postoperative infection compared with autologous blood transfusion or no transfusion. Using data from more than 12,000 patients assessed in the Phase-III RECORD (Regulation of Coagulation in Orthopedic Surgery to Prevent Deep Venous Thrombosis and Pulmonary Embolism) studies, the authors stratified patients into three groups according to the type of blood transfusion that they received: no transfusion (n = 6313), autologous blood transfusion (n = 1902), and allogeneic blood transfusion with or without autologous blood transfusion (n = 3962). The types of postoperative infection were recorded and included lower or upper respiratory tract and lung infection, bone and joint infection, wound inflammation or infection, urinary tract infection, and other infections. Based on the results of the study the same authors concluded that the rates of any infection, lower or upper respiratory tract and lung infection, and wound inflammation or infection were significantly increased after elective total hip or total knee arthroplasty in patients receiving allogeneic blood transfusion compared with those receiving autologous blood transfusion or no blood transfusion. (Friedman R, Homering M, Holberg G, Berkowitz SD. Allogeneic blood transfusions and postoperative infections after total hip or knee arthroplasty. *J Bone Joint Surg Am.* 2014 Feb 19;96(4):272-8. doi: 10.2106/JBJS.L.01268. PMID: 24553882).

RELATIONSHIP BETWEEN KUPPFER CELLS, INFLAMMATION, AND FIBROSIS IN CHRONIC HEPATITIS B AND C (Abstract): Kupffer cells are liver parenchymal components of the immune system able of intervention in pathogenic mechanisms involved in viral hepatitis and tumoral lesions. Our study aimed to evaluate the Kupfferian hyperplasia in chronic hepatitis B and C, and to correlate with the severity of liver lesions, focusing on the modality in which Kupffer cells modulate the necroinflammatory events and fibrosis specific for chronic hepatitis morphologic substrate. We investigated 33 cases with chronic hepatitis B and 38 cases with chronic hepatitis C, diagnosed according to Ishak score (in chronic hepatitis B and C) and METAVIR score (in chronic hepatitis C). Kuppfer cells were immunohistochemical labeled, by using an anti-CD68 antibody and heat-induced epitope retrieval (HIER) technique. The sinusoidal reaction expressed by CD68 (+) cells hyperplasia progressively increases along with the intensity of necroinflammatory activity and with the amplitude of fibrosis lesions. Statistically significant differences between Kupffer cells number and the degree of necroinflammatory activitiy and fibrosis, respectively (Ishak score) have been identified in both types of chronic hepatitis. However, no significant differences have been registered when comparing the Kupffer cells number corresponding to each degree of necroinflammatory activity and of fibrosis, in chronic hepatitis B *versus* C, respectively. Our results demonstrate the relationship between Kupffer cells and the severity degree of the disease, without differences between chronic hepatitis B and C. Consequently, we may appreciate that the chronic hepatitis C specific lesions progression, different from that of chronic hepatitis B, is influenced by a different behavior of Kupffer cells, and not by their effective number. **Keywords:** KUPFFER CELLS, CD68, CHRONIC HEPATITIS

A highly represented liver cells population had been firstly described in 1876, by Karl Wilhelm von Kupffer which he had named "Sternzellen" or stellate liver cells corresponding to their shape (1). These cells are considered as an intrinsic part of liver sinusoids endothelial cells and furthermore directly derived from them (1). Tadeusz Browicz had correctly defined the macrophagic characteristics of the stellate liver cells, in 1898; only after two decades researchers had named them as Browicz-Kupffer cells or simply Kupffer cells (2, 3). The blood that transits the liver is exposed

to approximately to $1.2x10^7$ Kupffer cells/tissue grams (4).

Kupffer cells are the main phagocytic cells and APC in liver sinusoid, being at the same time important sources of cytokines exhibiting locally chemotactic action or of stimulatory activity of endothelial and Ito cells. Classic studies have revealed the existence of Kupfferian population heterogeneity and consequently, in a normal liver status, Kupffer cells from the periportal region are larger and more actively involved in phagocytosis, while those from the centrilobular region are smaller and more actively involved in cytokine production and in cytotoxicity (5, 6). A deeper insight into these data have been added by recent immunological studies identifying 2 main types within Kupfferian cell population, namely a proinflammatory phenotype (M1) and another involved in resolution of the inflammatory phenomena in the liver parenchyma (M2) (7, 8).

Classically, light microscopy studies have revealed Kupffer cell hyperplasia in liver sinusoids during the sequence of immunological events characteristics for chronic viral hepatitis (9, 10). Although standard light microscopy reveals the Kupffer cells growth in liver sinusoid and even the „cells crowding" in specific territories, the precise appreciation of the intensity of this phenomenon could be only achieved by supplementary examinations, such as immunohistochemistry.

The purpose of our study is that of evaluation of the Kupfferian hyperplasia in viral chronic hepatitis with B hepatitis virus (HBV) and C hepatitis virus (HVC), respectively, and correlation of Kupfferian hyperplasia with the severity of liver lesions, focusing on the modality in which Kupffer cells modulate the necro-inflammatory events and fibrosis specific for chronic hepatitis morphologic substrate.

MATERIAL AND METHODS

The study group comprised 71 cases of chronic viral hepatitis (subgroup 1 – 33 cases with chronic hepatitis B, subgroup 2 – 38 cases with chronic hepatitis C), diagnosed in the Histopathology Laboratory of the Clinical Hospital of Infectious Diseases "St. Parascheva" Iași.

The cases selection has been achieved starting with the histopathologic diagnosis made according to Ishak score (in chronic hepatitis B and C) and METAVIR score (in chronic hepatitis C), respectively, having as a main criterion the frame into a severity class according to mild, moderate, and severe necroinflammatory activity (NIA). Thus, subgroup 1 included 10 cases characterized by mild necroinflammatory activity (score 1-6), 17 cases with moderate necroinflammatory activity (score 7-10), and 6 cases with severe necroinflammatory activity (score 11-18), and subgroup 2: 11 cases with mild necroinflammatory activity (score 1-6), 18 cases of moderate necroinflammatory activity (score 7-10), and 9 cases of severe necroinflammatory activity (score 11-18).

The studied group has been investigated by immunohistochemistry using an anti-CD68 antibody and heat-induced epitope retrieval (HIER) technique. The working protocol included: blockage of the endogenous peroxidase, incubation with the anti-CD68 antibody (clone KP1, Novocastra, Leica Biosystems) with a dilution ratio of 1:100, amplification with the secondary antibody and the Streptavidin–Biotin-Peroxidase HRP complex (Novocastra Novolink, Leica Biosystems), and counterstain with Mayer's Hematoxylin. The nega-

tive control was also performed.

The quantitative evaluation has been performed by two independent examiners, on 5 microscopic fields/case, using x 200 magnification. After the quantification of CD68 positive cells number for all examined areas, the median value obtained has been associated to the following scoring system (13, 14, 15): CD68 positive cells number < 10 cells – score 0; 10-49 CD68 positive cells number – score 1; 50-99 CD68 positive cells – score 2; ≥100 CD68 positive cells – score 3.

Student's *t*-test was used for all statistical comparisons.

RESULTS

Qualitative evaluation

The qualitative evaluation of CD68 positive cells distribution in sinusoids capillaries allowed the identification of the following aspects:

- the presence of a reduced number of CD68 positive cells, localized mainly in periportal sinusoidal spaces in patients diagnosed with mild activity type of chronic liver disease (fig. 1);

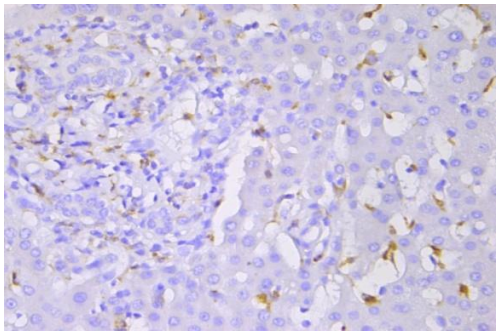

Fig. 1. Few CD68 positive cells in portal space and periportal sinusoids (IHC, x 40)

- the tendency of extension to the entire liver lobule and of CD68 focally concentration in specific "hyperplasia areas" in sinusoids, as closely tighten events to necroinflammatory lesions and portal and intralobular fibrosis enhancement (fig. 2).

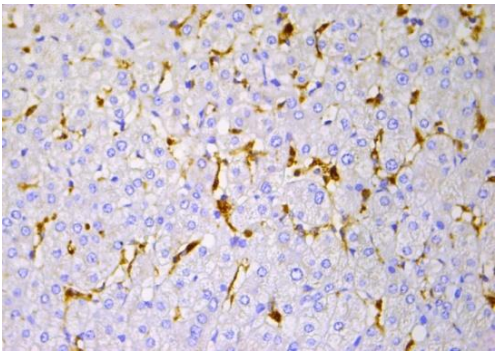

Fig. 2. Numerous intralobular CD68 positive cells, forming hyperplasia areas in sinusoid

Quantitative evaluation

The numerical results of the quantitative evaluation of Kupffer cells (median $\pm$ SD), related to the components of Ishak score (in both types of hepatitis) and of METAVIR score (in chronic hepatitis C), are summarized in table I and II.

Correlated to the numerical value correspondent to median and SD, the correspondent Kupffer cells score had, in both types of hepatitis, an ascendant trend related to the necroinflammatory activity (mild type - score 1 (24.54 $\pm$ 7.94), moderate type - score 2 (83.45 $\pm$ 28.44), and severe type - score 3 (126.45 $\pm$ 8.28)).

Differences between hepatitis B and C have been registered regarding the correlation to fibrosis (considering 1 and 2 score values for mild fibrosis and score values 3 and 4 for severe fibrosis). Thus, in chronic hepatitis B, Kupffer cells score had value 1 (31.96 $\pm$ 14.67) in mild fibrosis and value 3 (107.96 $\pm$ 18.87) in severe fibrosis, while in chronic hepatitis C mild fi-

brosis has been associated to a Kupffer cells score value of 1 (33.51 ± 14.69), and severe fibrosis - with a score of 2 (94.05 ± 31.37).

Related to Metavir score, exclusively applicable in chronic hepatitis C, we have noted the same increase of Kupffer cells number, thus cases with score A1F1/A1F2 being correlated to score 1 (30.64 ± 10.09), for cases with score A2F1/A2F2, Kupffer cells score being 2 (76.89 ± 18.36) and for cases with A3F3 –3 (119.62 ± 15.62).

Correlations between Kupffer cells and NIA – Ishak score

Statistically significant differences between Kupffer cells number corresponding to the 3 degrees of necro-inflammatory activities within mild *versus* moderate (p <

0.001), mild *versus* severe ($p < 0.001$), and moderate *versus* severe ($p < 0.001$) have been identified by Student t test, in both types of chronic hepatitis.

However, no statistically significant differences have been identified when comparing the Kupffer cells number corresponding to each degree of necroinflammatory activity and chronic hepatitis B *versus* C.

Correlations between Kupffer cells and fibrosis – Ishak score

In both types of chronic hepatitis, t Student test revealed the existence of significant differences between Kupffer cells number corresponding to the two grades of fibrosis, mild *versus* severe ($p < 0.001$). No statistically significant differences have been identified when comparing the Kupffer cells number corresponding to mild and sever fibrosis, in chronic hepatitis B evaluation versus chronic hepatitis C ($p < 0.001$).

Correlations between Kupffer cells and METAVIR score

Statistical analysis based on Metavir score, applied only in chronic hepatitis C revealed significant differences between Kupffer cells number corresponding to cases evaluated by A1F1/A1F2 score versus A2F1/A2F2 score versus A3F3 score ($p < 0.001$).

DISCUSSION

Kupffer cells and necroinflammatory activity – Ishak score

Kupffer cells are liver parenchyma components of the immune system able of intervention in pathogenic mechanisms involved in viral hepatitis and tumoral lesions, by their capacity to phagocyte antigens and to produce a panel of cytokines (16, 17, 18). They represent 15% of liver cell population and 80-90% of resident macrophages of human body (19).

Literature studies describe two mechanisms responsible for the conservation of Kupffer cells normal number in liver parenchyma in physiological conditions: attraction of new monocytes in liver sinusoids and their transformation into Kupffer cells and the multiplication of already existent Kupffer cells (19, 20).
